Preface

↓
The purpose of this research was to develop and validate a fallout prediction method using variable winds for particle transport calculations. The new method uses National Meteorological Center (NMC) spectral coefficients to compute wind vectors along the space and time varying trajectories of falling particles. The method was validated by comparing computed and actual cloud trajectories from a Mount St. Helens volcanic eruption and a high explosive dust cloud. → p. xi

The NMC supported this study by providing spectral coefficients for model development, sample wind vector data for model check-out and verification statistics for the accuracy assessment. I am grateful to LtCol John D. Warburton for his kind assistance and advice. In addition, I thank Maj James Kester and Lt Joyce White, ASD Staff Meteorologists, for obtaining the archived weather data used in the Mount St. Helens analysis.

I particularly thank Dr. Charles J. Bridgman, my advisor and research committee chairman, for his objective and constructive counsel throughout this dissertation study. I also thank the members of my research committee, Dr. George John, Dr. Dennis Quinn and Dr. David Auton, for their guidance and support.

This research was sponsored by the Defense Nuclear Agency (DNA). I gratefully acknowledge the support of DNA's technical library staff and the DIRECT COURSE project staff.

Not least, I thank Jeannie (my wife and word processor), Sarah and Patrick.

Arthur T. Hopkins

Abstract

A new method has been developed to incorporate variable winds into fallout transport calculations. The method uses spectral coefficients derived by the National Meteorological Center. Wind vector components are computed with the coefficients along the trajectories of falling particles. Spectral winds are used in the two-step method to compute dose rate on the ground, downwind of a nuclear cloud. First, the hotline is located by computing trajectories of particles from an initial, stabilized cloud, through spectral winds, to the ground. The connection of particle landing points is the hotline. Second, dose rate on and around the hotline is computed by analytically smearing the falling cloud's activity along the ground. The feasibility of using spectral winds for fallout particle transport was validated by computing Mount St. Helens ashfall locations and comparing calculations to fallout data. In addition, an ashfall equation was derived for computing volcanic ash mass/area on the ground. Ashfall data and the ashfall equation were used to back-calculate an aggregated particle size distribution for the Mount St. Helens eruption cloud. Further validation was performed by comparing computed and actual trajectories of a high explosive dust cloud (DIRECT COURSE). Using an error propagation formula, it was determined that uncertainties in spectral wind components produce less than four percent of the total dose rate variance. In summary, this research demonstrated the feasibility of using spectral coefficients for fallout transport calculations, developed a two-step smearing model to treat variable winds, and showed that uncertainties in spectral winds do not contribute significantly to the error in computed dose rate.

DEVELOPMENT AND VALIDATION OF A NEW FALLOUT TRANSPORT METHOD USING VARIABLE SPECTRAL WINDS

I. Introduction

Background

An atmospheric nuclear burst creates a cloud of vaporized radioactive particles composed of fission fragments, decay products, unfissioned bomb fuel and neutron-induced debris. The radioactive particles rise with the buoyant nuclear cloud, condensing on microscopic nuclei or on the surfaces of other particles. As condensed particles grow and the cloud cools, gravitational forces eventually exceed the forces induced by updraft, and the radioactive particles fall from the cloud. During their fall, particles are transported by ambient winds. As a result, radioactive fallout can land far from the point of weapon detonation. Fallout's widespread distribution coupled with its long-term nature make fallout transport modeling an important part of nuclear weapon effects studies.

Fallout transport studies have both military and civilian applications. Militarily, fallout may be an important consideration in studies of force recovery and organization after a strategic nuclear attack or during a protracted, limited nuclear war (69)(82). Fallout models are also used to estimate population exposure from past atmospheric nuclear weapons tests (8). In civilian applications, fallout models are applied to study population survival and economic recovery prospects following a nuclear attack (30)(42)(56)(60)(66)(76). Currently, fallout transport

models are even used to estimate potential climatological effects of global nuclear fallout and dust, the "nuclear winter" (105).

Fallout Models

Fallout studies use both numerical and analytic methods to predict particle motion in the atmosphere and dose rates on the ground. The standard numerical fallout code for military applications is DELFIC, the Defense Land Fallout Interpretative Code (79). DELFIC computes cloud rise, growth, stabilization and transport, with detailed simulation of radioactive particle formation. Particle fall is computed in a wind field that is (optionally) spatially constant, spatially constant with temporal updates or spatially interpolated within a finite grid of wind profiles. DELFIC is frequently used as a computational benchmark for simpler analytic models, such as the AFIT (Air Force Institute of Technology) and WSEG (Weapon Systems Evaluation Group) codes (17)(19)(78)(85)(86).

AFIT and WSEG simulate the fallout process by smearing (depositing) the falling cloud's radioactivity on the ground unidirectionally downwind. The analytic codes assume a constant wind vector to transport the cloud (49)(65). The constant wind assumption is a significant source of error, particularly when winds are not nearly constant in time and space.

Particle Transport in Spectral Winds

This report presents a new way to compute particle transport using variable winds. The new method uses spectral coefficients currently generated by the National Meteorological Center (NMC) and soon to be generated by the Air Force Global Weather Central (AFGWC)(103). Spectral coefficients are derived from global wind data collected twice daily,

nearly simultaneously. By fitting the wind data with a truncated series of spherical harmonics, NMC reduces the data to a set of complex spectral coefficients. The coefficients are used in the spherical harmonics expansions to compute wind speeds (spectral winds) anywhere in the atmosphere.

With spectral winds, fallout transport is modeled by computing wind speeds from coefficients at discrete positions and times along the trajectories of falling particles. Horizontal spatial variability is naturally simulated by the harmonic polynomials. There are coefficient sets for each of twelve different altitudes, so winds (or coefficients) must be vertically interpolated to obtain wind speeds between spectral heights. Each coefficient set fits the polynomials to global wind data at a fixed time, so winds (or coefficients) can be temporally interpolated to estimate wind speeds at times when data was not collected.

Using spectral winds to compute fallout particle trajectories will vastly improve the accuracy of fallout prediction codes. Spectral winds represent real atmospheric wind data over the entire globe. Particle trajectories can be computed with continuous, four dimensional variability.

Analytic Fallout Code with Variable Winds

Spectral winds can be used in any numerical or analytic fallout code. The spectral wind equations are ideally suited for calculations of wind-driven particle motion in a Lagrangian reference frame. A numerical fallout code with spectral wind transport would be an ideal fallout prediction system, coupling a state-of-the-art physics model with global, variable winds. However, DELFIC, the standard numerical fallout code is so large and slow that it is impractical to use for most fallout studies,

especially when many hypothetical bursts are being considered. Analytic codes, such as AFIT and WSEG, are used for most fallout studies because they are economical, fast-running and benchmarked against DELFIC and actual fallout data (19)(69)(81)(84). In this study, spectral wind transport is incorporated into an analytic fallout code.

The AFIT and WSEG analytic fallout codes were designed for simplified cloud transport with a single wind vector. A new analytic method was developed to compute fallout dose rates with variable winds (53). The new method is a two step approach. First, the radioactive hotline is located by tracking the motion of particles from an initial, stabilized cloud, through spectral winds, to the ground. The hotline is the locus of peak activity downwind of the burst. Second, dose rate is calculated with a solution to the two-directional dose rate integral equation:

$$\dot{D} = k Y ff \int_0^{\infty} f(x,y,t) g(t) dt \quad (1.1)$$

where

- \dot{D} = dose rate at (x,y) at one hour after burst
note: \dot{D} is called dose rate in this report to be consistent with most fallout references. Actually, \dot{D} is the dose rate to air, or exposure rate, as defined by the International Commission on Radiation Units.
- k = source normalization constant, typically 2350 (Roentgens/hour) (square miles/kiloton)
- Y = weapon yield (kilotons)
- ff = fission fraction
- f(x,y,t) = spatial distribution function
- g(t) = activity arrival rate function

With the two step method, cloud radioactivity is analytically smeared along the ground on and around a curved hotline defined by explicit particle fall calculations through variable, spectral winds.

Organization of Report

Chapter II explains how the NMC derives spectral coefficients, and how wind vector components are computed from the coefficients. Chapter III describes the hotline locator model that uses spectral winds to transport falling particles from the initial cloud to the ground. A variable wind fallout code is presented in Chapter IV, with an algorithm to compute dose rate at arbitrary field points. Chapter V shows results of two validation studies, using data from a Mount St. Helens ash cloud and from a cloud produced by a large high explosive (not nuclear) atmospheric burst. An error analysis is presented in Chapter VI, quantifying the effects of uncertainties in wind speed (and other independent variables) on dose rate at a point.

Appendix A shows a sample of spectral coefficients for the 1000 millibar height at 00UT (Universal Time) 16 Jan 82. Appendix B contains the derivation of the equation for computing spectral winds. Appendix C illustrates how different nuclear models position the stabilized cloud in the atmosphere. Polynomials for computing the Laurent series coefficients (used to determine particle sizes arriving downwind) are in Appendix D. Appendix E contains an integration of cloud activity in the cross-wind direction. The algorithm for off-axis dose rate determination is in Appendix F. Appendix G explains how particle size distributions are fitted with trimodal log-normal distributions, using a constrained minimization search in the nine parameter hyperspace defined by the sum of three log-normal distribution functions.

II. Spectral Wind Calculations

In this report, spectral winds are the wind vector components obtained from NMC spectral coefficients. This chapter describes the source of the coefficients and the equations for computing wind vectors.

NMC Spectral Coefficients

Numerical models of atmospheric motion were developed by the NMC and others to study the general circulation of the atmosphere and to generate forecasts. Atmospheric motion is modeled by NMC with a set of non-linear partial differential equations that describe the temporal variation of space-dependent atmospheric variables (37)(71). The partial differential equations are converted to ordinary differential equations, then solved by finite difference techniques (15)(32)(34)(83). Space-dependent atmospheric variables in the partial differential equations are replaced by spherical harmonic expansions of the form (89)(93)(95):

$$D = \sum_{\ell=-J}^J \sum_{n=|\ell|}^{|\ell|+J} D_n^{\ell} P_n^{\ell}(\sin\phi) \text{EXP}(i\ell\lambda) \quad (2.1)$$

where

D = space (and time) dependent atmospheric variable

D_n^{ℓ} = complex expansion (spectral) coefficient

P_n^{ℓ} = associated Legendre polynomial

ϕ = latitude

λ = longitude

ℓ = zonal (latitudinal) index

n = ordinal (longitudinal) index

J = truncation limit

Substituting a series like Eq (2.1) for each space-dependent variable transforms the partial differential equations into a set of ordinary differential equations, with time as the independent variable. The truncation limit, J , is selected by NMC to be high enough for accurate forecasts that are independent of the truncation limit (87).

As defined in the summations, allowable values of l and n are bounded within a rhomboid on a plot of l vs n . Rhomboidal truncation is used primarily because it gives the same number of meridional components for each zonal index (wave number) (35)(94).

Time integration of the differential equations requires initial values of the expansion coefficients, D_n^l . The initial coefficients are computed by NMC using observed global atmospheric data and the normalization integral for spherical harmonics (95). The initial spectral coefficients fit the truncated spherical harmonics to observed global wind data that is collected twice daily. Coefficients can be used to compute the observed wind data and to interpolate the data on a spherical earth.

A set of spectral coefficients is derived for each wind component, u and v , at each of twelve heights in the atmosphere at a fixed time. Figure II-1 shows the spectral heights. Individual sets of coefficients are not empirically or analytically related in the NMC spectral models of atmospheric motion. However, the data used to derive the coefficients comes from continuous vertical soundings, so spectral winds will have an inherent inter-altitude correlation at a fixed time. The NMC has demonstrated that the spectral wind structure is vertically consistent (70). Therefore, particle trajectories, passing through spectral winds at

0.1		1000
ABOVE SEA LEVEL		

Figure II-1. Spectral Heights and Pressure Levels

various altitudes, should be smooth and continuous.

Appendix A shows some spectral coefficients for the 1000 millibar height at 00UT (Universal Time) on 16 Jan 82. They are for the u-component of wind; 63 complex pairs are shown. A complete set of coefficients for all twelve atmospheric heights, at one time, consists of 23808 complex pairs. Spectral coefficients are routinely archived by NMC at the National Climatic Center, Asheville, North Carolina.

Wind Calculation

With the spectral coefficients for a specific date, time and pressure level, wind vector components can be computed anywhere in the atmosphere using the spherical harmonics expansion (95)(112):

$$(U,V) = (u,v) \cos \phi = \sum_{\ell=-J}^J \sum_{n=|\ell|}^{|\ell|+J+1} (U_n^\ell, V_n^\ell) P_n^\ell(\sin \phi) \text{EXP}(i\ell\lambda) \quad (2.2)$$

where

(U,V) = pseudo-wind components, either U or V
 (u,v) = spectral wind components, either u or v
 u = west to east
 v = south to north
 (U_n^ℓ, V_n^ℓ) = spectral coefficients, either U_n^ℓ or V_n^ℓ

By rearranging the summation and using identities for spherical harmonics, the spectral equations become:

$$\begin{aligned} (U,V) &= (u,v) \cos \phi \\ &= \text{Re} \sum_{\ell=0}^J A \sum_{n=\ell}^{\ell+J+1} (U_n^\ell, V_n^\ell) P_n^\ell(\sin \phi) (\cos \ell\lambda + i \sin \ell\lambda) \end{aligned} \quad (2.3)$$

where

$$\begin{aligned} A &= 1 && \text{if } \ell = 0 \\ A &= 2 && \text{otherwise} \end{aligned}$$

See Appendix B for the stepwise derivation of Eq (2.3) from Eq (2.2).

Appendix B also shows the recursion relation for the associated Legendre polynomials, and the computational algorithm for spectral winds.

Figures II-2 through II-13 show fields of wind vectors computed with spectral coefficients at each of the twelve levels. Vectors were computed with Eq (2.3) on $2\frac{1}{2}$ degree intervals in latitude and longitude. High winds associated with the jet stream are easily seen in Figures II-7, 8 and 9 near tropopause heights. The coefficients can be used to compute winds at any global location where fallout or cloud transport predictions are needed.

Truncation

Current NMC models use $J = 30$, so there are 31 zonal indices (ℓ) and 32 ordinal indices (n) for each ℓ . Alternate truncations were examined in this study to determine how abbreviation of (ℓ, n) space affected wind speed calculations (4). Figure II-14 shows alternate rhomboidal truncations of $J = 27, 24, 21, 18$ and 15 . Wind vectors were computed at 189 northern hemisphere points at the 1000 millibar level with each truncation, noting the average deviation of each component's magnitude from the corresponding $J = 30$ component's magnitude. This is shown in Figures II-15 and II-16. Deviations were largest when $J < 24$, and v component deviations were generally larger than u component deviations. Most significantly, winds less than 1 meter per second (mps) were much more affected by truncation than winds greater than 1 mps. A truncation to $J = 24$ produces

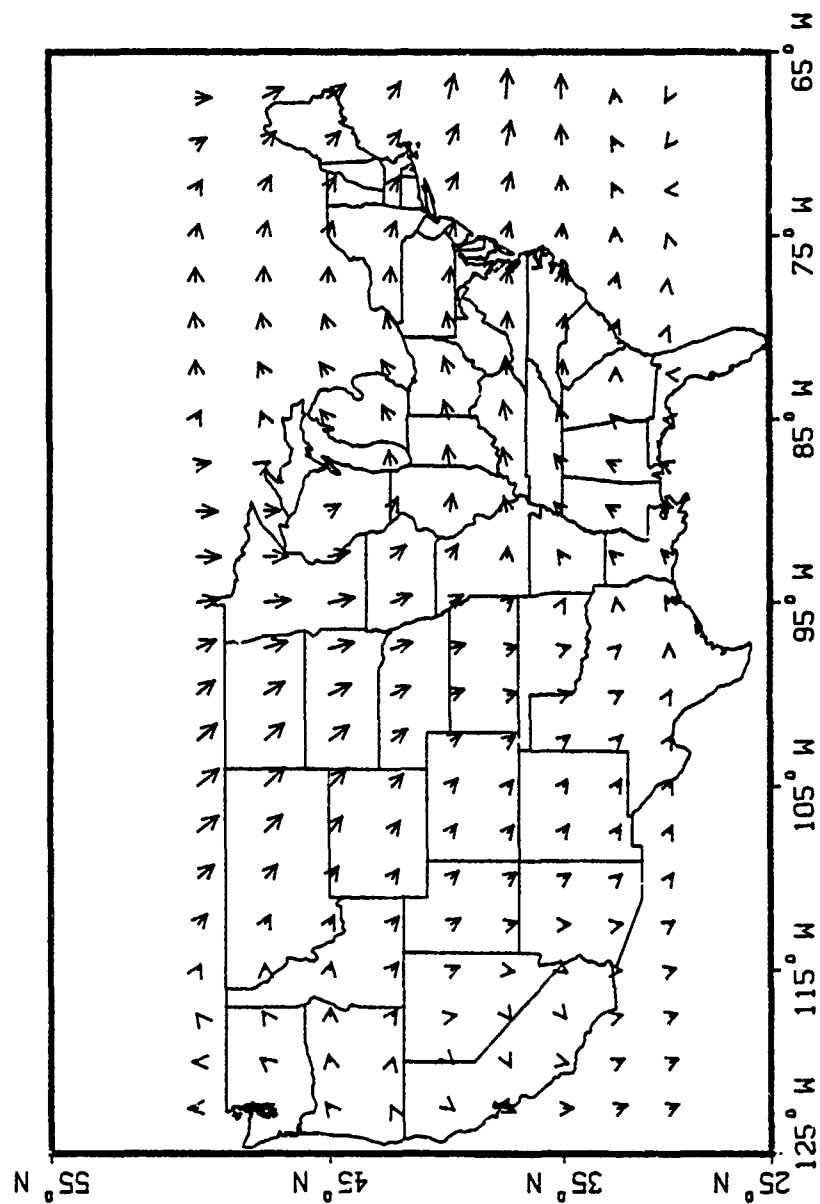

Figure II-2. Spectral Wind Vector Field, 1000 mb

Figure II-15. Truncation Effect on U Wind Component

Figure II-16. Truncation Effect on V Wind Component

an average deviation of $\pm 50\%$ (all winds), but only $\pm 5\%$ considering only winds greater than 1 mps. Abbreviating the summations would require fewer calculations per component than setting $J=30$, but the error introduced in low velocity winds may cause large errors in hotline placement. Spectral wind calculations in this report use $J=30$.

Accuracy of Spectral Winds

The NMC routinely verifies that the spectral winds do represent the radiosonde data used to derive the coefficients (70)(108)(109)(110)(111). A measure of accuracy is the root-mean-squared (rms) vector error:

$$\Delta w = \frac{1}{N-1} \sum_{i=1}^N [(u - u_r)^2 + (v - v_r)^2]^{\frac{1}{2}} \quad (2.4)$$

where

Δw = rms vector error
 (u, v) = spectral wind components
 (u_r, v_r) = radiosonde wind components

The rms vector error is determined by NMC monthly using spectral winds and radiosonde data. Table II-1 shows the maximum, minimum and average rms vector errors, for four levels, based on 25 consecutive months' data. RMS vector errors are derived from data taken by 110 North American weather observation stations.

The vector errors do not vary significantly with height, but wind speed generally increases with height. Therefore, the relative error, ratio of vector error to wind vector magnitude, should decrease with increasing height. This expectation is validated in Chapter V, with a comparison between the spectral wind trajectory and the actual trajectory of a 3 kilometer high cloud.

TABLE II-I

RMS Vector Errors
(Meters per Second)

<u>Level</u>	<u>Altitude</u>	<u>RMS Vector Error</u>

250	10.4	6.8	6.0	7.9
100	16.2	3.7	2.9	4.8

III. Hotline Locator Model

A two step method is used to model variable wind effects with a smearing fallout code. First, the hotline is located; then, activity is smeared downwind, along the hotline. This chapter describes how hotline coordinates are computed, using spectral winds. Essentially, a particle array is tracked from the initial stabilized cloud, through spectral winds, to the ground. Wind-driven horizontal displacements of each falling particle are computed and summed through a discretely layered atmosphere. The hotline is the connection of particle landing points. Different sized particles fall from different initial heights with different speeds through different winds, so hotlines may be curved.

Following is a description of the initial cloud, atmosphere discretization and fall-speed calculation used to locate the hotline. Wind shear is also computed along particle trajectories for use in smearing code estimates of cloud spreading. Sample hotlines are shown for hypothetical clouds that start above land-based missile sites in the United States.

Initial Cloud

Initially, the stabilized cloud contains all radioactive particles. The cloud model is a gravity-sorted distribution of particle size vs height, obtained from correlations of DELFIC cloud height data (11). Figure III-1 shows how particle size varies with height in initial clouds produced by five different nuclear weapon yields. Particle size and height in the cloud are linearly related; slopes and intercepts

Figure III-1. Average Heights of Particles in DELFIC's Stabilized Clouds

are yield-dependent polynomials. Equations for particle height, slope and intercept are in Appendix C.

Assuming that particle starting heights represent altitudes of peaks in constant-size activity distributions, the ground trace of particles describes the fallout hotline. This assumption was validated in (53) by comparing hotlines from initial cloud correlations with DELFIC results.

In this report, initial clouds are the gravity-sorted clouds shown in Figure III-1. In fact, there are many independent estimates of initial cloud heights, based on numerical and empirical data. The distributed size-height correlations are used because they replicate DELFIC's initial clouds, and they generally agree with observed data. Other initial clouds can and have been used for fallout calculations with analytic codes. Appendix C presents some initial cloud models and shows cloud height sensitivity to weapon yield.

Atmosphere Discretization

The atmosphere is divided into layers of equal thickness beneath the height of the highest (smallest) particle in the initial cloud. Particle trajectory calculations showed that hotline location varied with assumed number and thickness of atmosphere layers in the hotline locator model. However, sensitivity studies with 3, 6, 12, 24, 36, and 48 layer models indicate that hotline coordinates change very little with more than 24 layers.

Hotline coordinates were computed with the six different layer models using the same particle sizes in each model. Coordinates varied less as atmosphere discretization became finer. The deviation in

distance from the burst point was used to quantify the variation in hotline coordinates with number of model layers. See the inset on Figure III-2. Average deviation is the average of deviations of twelve hotline points. Figure III-2 shows how the average deviation decreased with increasing number of model layers. Hotline coordinates were nearly stationary with 24 or more model layers; the average deviation due to increasing the number of model layers above 24 was less than 4%.

Atmosphere properties are computed at each level with state equations for a U.S. Standard Atmosphere (75)(107). The equations are summarized in (53). Particle fall speeds are computed at each level and averaged between levels to obtain a fall speed and residence time in each layer of atmosphere. The product of wind speed and residence time gives displacement within a layer; displacements are summed in all layers between the particle's initial height and the earth surface.

Wind speed at any latitude, longitude and height is computed with spectral coefficients and Eq (2.3). This hotline locator model linearly interpolates (in height) spectral winds to obtain wind vector components in a layer of atmosphere. The interpolated winds transport falling particles to new horizontal coordinates at a lower level in the discrete atmosphere. Figure III-3 shows the relations among the discrete atmosphere, a megaton initial cloud and the spectral wind heights.

Particle Fall Rate

The terminal velocity of each particle must be calculated at each level to obtain the particle's residence time in each discrete layer of atmosphere. Terminal velocities are calculated with the Davies-McDonald method (27)(67)(68). Davies empirically related

Figure III-2. Average Deviation of Hotline Coordinates vs Change in Number of Model Layers

Figure III-3. Atmosphere Discretization, Initial Cloud and Spectral Heights in Hotline Locator Model

the Reynolds number, Re , of a moving sphere to $C_D Re^2$; C_D is the particle's drag coefficient. McDonald described an algorithm to compute the quantity $C_D Re^2$ from particle size, particle density, atmospheric density and kinematic viscosity. Using $C_D Re^2$ to obtain Re , terminal velocity is computed as follows:

$$V_z = Re \, \nu / d \quad (3.1)$$

where

V_z = terminal velocity
 Re = Reynolds number
 ν = atmospheric kinematic viscosity
 d = particle diameter

The equations assume that particles are spheres of constant density falling through the discretely layered atmosphere. Figure III-4 shows the total fall time of ten different sized particles from heights up to 18 kilometers above sea level in a U.S. Standard Atmosphere.

Wind Shear

Vertical wind shear is a measure of the wind field's dispersive effect on the falling cloud. Components of the shear vector are defined as follows (43)(48):

$$s_x = \Delta u / \Delta z \quad (3.2)$$

$$s_y = \Delta v / \Delta z \quad (3.3)$$

where

s_x = vertical shear (westerly)
 s_y = vertical shear (southerly)
 Δz = finite thickness of atmosphere
 $(\Delta u, \Delta v)$ = wind component variations over Δz

Figure III-4. Particle Fall Times from Heights up to 18 Kilometers

Wind shear is a characteristic frequency with which atmospheric turbulence acts on the cloud (6)(7). For nuclear clouds, the turbulence scale is assumed to be a fraction of the initial cloud thickness. Fallout codes usually assume a constant shear value for the life of the cloud (86). The constant shear is typically either a guess or a number calculated from the vertical profile that was used to compute the constant, 'effective' wind.

However, spectral winds permit separate shear calculations for each point on the hotline. Shear then represents the net dispersive effect of cloud-scale turbulence on individual particle size groups in separate trajectories. For each hotline point (or particle size), shear is computed as follows:

$$(S_x, S_y) = \left(\sum_i (s_x, s_y)_i^2 \frac{t_i}{TFALL} \right)^{\frac{1}{2}} \quad (3.4)$$

where

(S_x, S_y) = net (rms) shear in trajectory

t_i = residence time of particle in layer i

TFALL = total fall time of particle from initial cloud to ground

Net shear (S_x, S_y) is the rms value of shears determined over discrete layers of atmosphere, weighted by the residence time of each particle in each layer of atmosphere.

Sample Hotlines

Figure III-5 shows hotlines computed with a twenty-four layer hotline locator model that tracks twenty particles. The model uses spectral coefficients to compute the winds that transport falling particles in a U.S. Standard Atmosphere. Initial earth coordinates of the stabilized

Figure III-5. Curved Hotlines with Variable Winds in Hotline Locator Model

cloud are specified as colatitude and longitude east of Greenwich in radians. The hotlines are continuous and realistically curved. Points on the hotline are landing spots of different particle sizes; large particles fall closer to the burst point.

Summary

A hotline locator model was developed to compute hotline coordinates. The model uses spectral wind coefficients to compute wind vectors and shear along the trajectories of falling particles. Sensitivity studies show that computed hotline points converge to stationary locations as the number of atmospheric layers increase. Twenty-four discrete layers beneath the highest particle in the initial cloud give adequate convergence. Wind shear is computed from each particle's unique trajectory winds. Sample hotlines are continuous and realistically curved.

Key model assumptions are as follows:

- (1) U.S. Standard Atmosphere
- (2) Linear vertical interpolation of winds between spectral heights
- (3) No updrafts or downdrafts
- (4) Constant density (2.6 grams per cubic centimeter) spheres

These assumptions were made to generate the illustrative hotlines shown here. Actually, any appropriate atmosphere, interpolation scheme, vertical velocity and particle density can be used to compute hotline location.

IV. Variable Wind Smearing Model

This chapter describes the second step necessary to determine fallout dose rate with variable winds. A fallout smearing model is presented that determines ground coordinates of dose rate contours around curved hotlines. Curved hotline coordinates were computed separately in the first step with the hotline locator model (Chapter III), using spectral winds for particle transport.

Existing smearing codes use a constant wind vector to transport a falling cloud of radioactive particles unidirectionally downwind. The one dimensional dose rate equation for smearing codes cannot be used with variable winds because a constant wind was assumed to obtain the analytic solution for dose rate (19). With variable winds, cloud activity is smeared along a curved hotline, using a new analytic solution to the dose rate integral.

Following sections describe the dose rate equation, its activity arrival rate term and its spatial distribution term. A method is developed to compute dose rate at any specified ground location. Sample contours of constant dose rate about curved hotlines are shown.

Dose Rate Equation

Dose rate is computed with an analytic solution to the dose rate integral, Eq (1.1). Following is the dose rate equation:

$$\dot{D} = \frac{k Y_{ff} g(ta)}{\sqrt{2\pi}} (\sigma_x^2 V_y^2 + \sigma_y^2 V_x^2)^{-\frac{1}{2}} \exp \left(-\frac{1}{2} \frac{(x V_y - y V_x)^2}{\sigma_x^2 V_y^2 + \sigma_y^2 V_x^2} \right) \quad (4.1)$$

where

k = source normalization constant
 Y = kilotons of weapon yield
 ff = fraction of weapon yield from fission
 $g(t_a)$ = arrival rate of activity on ground (hour⁻¹)
 (X,Y) = hotline coordinates (miles from burst point)
 (x,y) = ground coordinates where dose rate is calculated
 (miles from burst point)
 (V_x, V_y) = net wind components from burst point to hotline
 point (X,Y) (miles/hour)
 (σ_x, σ_y) = deviations of cloud activity distributions (miles)
 note: x direction is positive eastward
 y direction is positive northward

Eq (4.1) was obtained by assuming that cloud activity is distributed normally in two directions, and that the arrival rate function, $g(t)$, can be approximated with a two-term Taylor expansion about arrival time, t_a (19)(53). Furthermore, analytic integration of Eq (1.1) required that dose rate be computed at points distant from the burst point.

A constant, unidirectional wind is simulated when $V_y=0$ and $V_x=$ constant at all hotline points. The dose rate equation then reduces to the unidirectional, constant wind form in (19); setting $V_y=0$, the dose rate equation becomes:

$$\dot{D} = \frac{k Y ff g(t_a)}{\sqrt{2\pi} \sigma_y V_x} \text{EXP} \left[-\frac{1}{2} \frac{y^2}{\sigma_y^2} \right] \quad (4.2)$$

Activity Arrival Rate

Cloud activity is smeared along the ground as the falling cloud translates with the winds. The activity arrival rate function, $g(t)$, is the functional rate of arrival of activity on the ground (19).

$$g(t) = -A(r) \frac{dr}{dt} \quad (4.3)$$

Assuming that a log-normal distribution describes the particle number-size frequency in the cloud, the activity-size distribution function can be expressed as the sum of two distributions (2)(19).

$$A(r) = A_3 + A_2 \quad (4.4)$$

$$A_3 = \frac{fv}{\sqrt{2\pi} \beta_3 r} \text{EXP} \left[-\frac{1}{2} \left(\frac{\ln r - \alpha_3}{\beta_3} \right)^2 \right] \quad (4.5)$$

$$A_2 = \frac{1 - fv}{\sqrt{2\pi} \beta_2 r} \text{EXP} \left[-\frac{1}{2} \left(\frac{\ln r - \alpha_2}{\beta_2} \right)^2 \right] \quad (4.6)$$

where

fv = fraction of cloud activity that is volume-distributed in particles

$1-fv$ = fraction of cloud activity that is surface-distributed on particles

r = particle radius

β = slope of log-normal distribution

$\alpha_n = \alpha_0 + n \beta^2$ = logarithm of median radius in n^{th} moment distribution

$\alpha_0 = \ln r_0$ = logarithm of median radius in particle number-size frequency distribution

$\frac{dr}{dt}$ = time derivative of particle radius arriving on ground

$A(r)$ thus represents the fractionation or apportionment of cloud activity onto the surfaces (A_2) and throughout the volumes (A_3) of the particles.

Figure IV-1 shows A_3 , A_2 and $A(r)$ for typical values of $fv = 0.68$, $\beta = 1.386$ and $r_0 = 0.204$ (17)(19)(78). Figure IV-2 shows the same activity distributions weighted by particle radius.

The time derivative of particle size arriving at each hotline point, dr/dt , is computed with a Laurenx series developed to compute the particle size arriving from the initial cloud at specified times (24).

Figure IV. 1. Particle Activity-Size Distributions for Nuclear Cloud

Figure IV-2. Particle Activity-Size Distributions
Weighted with Particle Size

$$\frac{dr}{dt} = \sum_{i=1}^5 C_i (i-6) t^{i-7} - \frac{1}{2} C_7 t^{-\frac{3}{2}} \quad (4.7)$$

where

C_i = Laurent series constants (height dependent)
 τ_i = arrival time of particle size r from a specified height

Each Laurent series constant (C_1 through C_7) was correlated with height, so each constant can be computed with a sixth degree polynomial. The polynomials eliminate the need for tabular searches for C_i values. Appendix D contains the polynomial constants needed to calculate the Laurent series constants.

Since particles in the initial cloud are gravity-sorted, different particle sizes fall from different initial heights. A different set of Laurent series constants for each particle size can be computed with the polynomials. Thus, the distributed initial cloud is modeled with a stack of pancake clouds, one for each particle size. The pancake clouds are simple, accurate approximations of vertical activity distributions that are symmetric about the pancake cloud height (12). The pancake cloud computations of dr/dt with Laurent series are appropriate only for fallout particles with mass densities of 2.6 grams per cubic centimeter.

For other particle mass densities, dr/dt can be computed with the discrete particle arrival times generated by the hotline locator. Numerical differentiation using r and t , can produce any dr/dt along the hotline (74). Figure IV-3 shows dr/dt computed three ways for a megaton initial cloud: (1) Laurent series for pancake cloud, (2) Laurent series for a stack of pancake clouds at DELFIC distributed heights, and (3) numerical derivatives (central differences). Numerical values of

Figure IV-3. Time-Derivative of Particle Size
Arriving from Initial Cloud

dr/dt were computed with radii and arrival times from a hotline location calculation. Distributed clouds give essentially the same dr/dt as a simple pancake initial cloud, except at early times (< 1 hour) when large particles are arriving from low altitudes.

Spatial Distribution

The spatial distribution function describes the lateral distribution of activity in the cloud.

$$F_{xy} = \frac{1}{\sqrt{2\pi} \sigma_V} \text{EXP} \left[-\frac{1}{2} \left(\frac{x V_y - y V_x}{\sigma_V} \right)^2 \right] \quad (4.8)$$

$$\sigma_V^2 = \sigma_x^2 V_y^2 + \sigma_y^2 V_x^2 \quad (4.9)$$

Figure IV-4 illustrates F_{xy} over a plane, with constant net wind components, V_x and V_y .

This two directional normal distribution defines the spread of activity along a line perpendicular to the net wind vector (8). Figure IV-5 shows the geometry of the net wind and crosswind lines.

The ground position (x,y) is on the net crosswind line. Activity is smeared simultaneously onto the net crosswind lines as the cloud moves downwind along the hotline. The spatial distribution function, F_{xy} , contains a normalized Gaussian spread in the net crosswind direction. Dispersing clouds in the atmosphere are typically modeled with normal lateral distributions. Data from aircraft sampling supports this Gaussian model (29). Appendix F contains an integration of F_{xy} along a net crosswind line, illustrating normalization in the crosswind direction.

Figure IV-4. Three Dimensional Plot of Spatial Distribution Function

Figure IV-5. Net Wind and Hotline Geometry

The deviation, σ_y , suggests an ellipse-shaped ground intercept of the cloud with eccentricity determined by net wind components and directional deviations. In fact, dispersion theory and observations of nuclear clouds suggest an ellipse-shaped spatial distribution. Aircraft sample data from nuclear clouds produced by Chinese atmospheric nuclear tests showed that debris clouds were ellipse-shaped in horizontal directions at aircraft altitudes (104).

Lateral Deviations

Standard deviations of the fallout cloud activity are specified in the x and y directions; x is positive eastward and y is positive northward. The deviations are functions of initial cloud size, toroidal growth and wind shear effects. The initial cloud size is determined by weapon yield. Toroidal growth continues until the cloud's internal flow stops. Late time cloud growth is driven by wind shear. Following are equations for crosswind deviation, σ_y , given by Pugh (86) for a constant wind, V_x :

$$\sigma_y^2 = \sigma_0^2 \left(1 + 8 \frac{T_s}{T_c} \right) + (t S_y \sigma_h)^2 \quad (4.10)$$

where

σ_0 = initial cloud parameter

$$\ln \sigma_0 = 0.7 + \frac{\ln Y}{3} - 3.25 / [4.0 + (\ln Y + 5.4)^2] \quad (4.11)$$

Y = yield (megatons)

T_s = elapsed time for toroidal growth = t if $t \leq 3$ hours

T_c = effective e-folding time for activity arrival on the ground;
based on exponential $g(t)$ in Pugh (86)

$$= 12 \left(\frac{HC}{60} \right) - 2.5 \left(\frac{HC}{60} \right)^2 \quad (\text{hours})$$

$$\begin{aligned}
HC &= 44.0 + 6.1 \ln Y - 0.205 (\ln Y + 2.42) |\ln Y + 2.42| \quad (\text{kilo feet}) \\
\sigma_h &= 0.18 HC \\
t &= \text{cloud arrival time} \\
S_y &= \text{wind shear in } y \text{ direction} \quad (\text{hours}^{-1})
\end{aligned}$$

The first term in Eq (4.10) models toroidal growth, which is assumed to stop at 3 hours after the burst. The second term represents growth due to wind shear. Figure IV-6 shows how σ_0 , T_c and HC vary with weapon yield.

With variable winds, downwind is not likely to be in the x direction at all times. The spatial distribution function, F_{xy} , requires σ_y and σ_x to determine the crosswind spread of activity. Therefore, σ_x is computed with an equation analogous to σ_y .

$$\sigma_x^2 = \sigma_0^2 \left(1 + 8 \frac{T_s}{T_c} \right) + (t S_x \sigma_h)^2 \quad (4.13)$$

The x and y direction shears are computed from spectral winds using the hotline locator model. Shear is determined along each particle's unique trajectory through variable winds.

In general (after 3 hours), σ_x and σ_y are proportional to t . This linear dependence is stronger than diffusion theory predicts. Many models of cloud dispersion in the atmosphere assume Fickian diffusion (20)(96), and the analytic solution to the diffusion equation gives a Gaussian form with σ defined as follows:

$$\sigma = (2 K t)^{\frac{1}{2}} \quad (4.14)$$

where

σ = standard deviation of cloud distribution
 K = coefficient of eddy diffusivity

Figure IV-6. WSEG Yield-Dependent Parameters

Eddy diffusivity coefficients have been estimated for nuclear clouds (6) (64). With falling particles, the cloud dispersion process is affected by vertical wind shear, so the diffusivity, K , must be an effective value accounting for shear, fall and diffusion (63)(102)(117).

Sample contours in this report were computed with Pugh's specification for σ_y , because his formula was based on nuclear cloud data and because it contains explicit weapon yield dependence.

Dose Rate Calculations

The variable wind smearing model determines fallout dose rate at a point. Coordinates of a desired dose rate are found by marching away from hotline points (X,Y) , along net crosswind lines, until computed dose rate at (x,y) is the desired level. Figure IV-7 shows the geometry for finding a dose rate contour; the line connecting each point (x,y) is the contour. Figure IV-8 shows 0.3 Roentgen/hour dose rate contours computed with the curved hotlines shown in Chapter III.

To compute dose rate at any arbitrary ground point (x,y) , it is necessary to find the hotline point (X,Y) that is connected to (x,y) on a crosswind line. Using the fact that the burst point $(0,0)$, hotline point (X,Y) and ground point (x,y) form a right angle, a method was developed to find (X,Y) for any (x,y) . Appendix F presents the technique for finding the hotline point (X,Y) associated with any ground point (x,y) . Figure IV-9 shows a three-dimensional dose rate surface computed with this technique at 1000 arbitrary points downwind of a megaton yield nuclear burst.

Figure IV-7. Dose Rate Contour Geometry

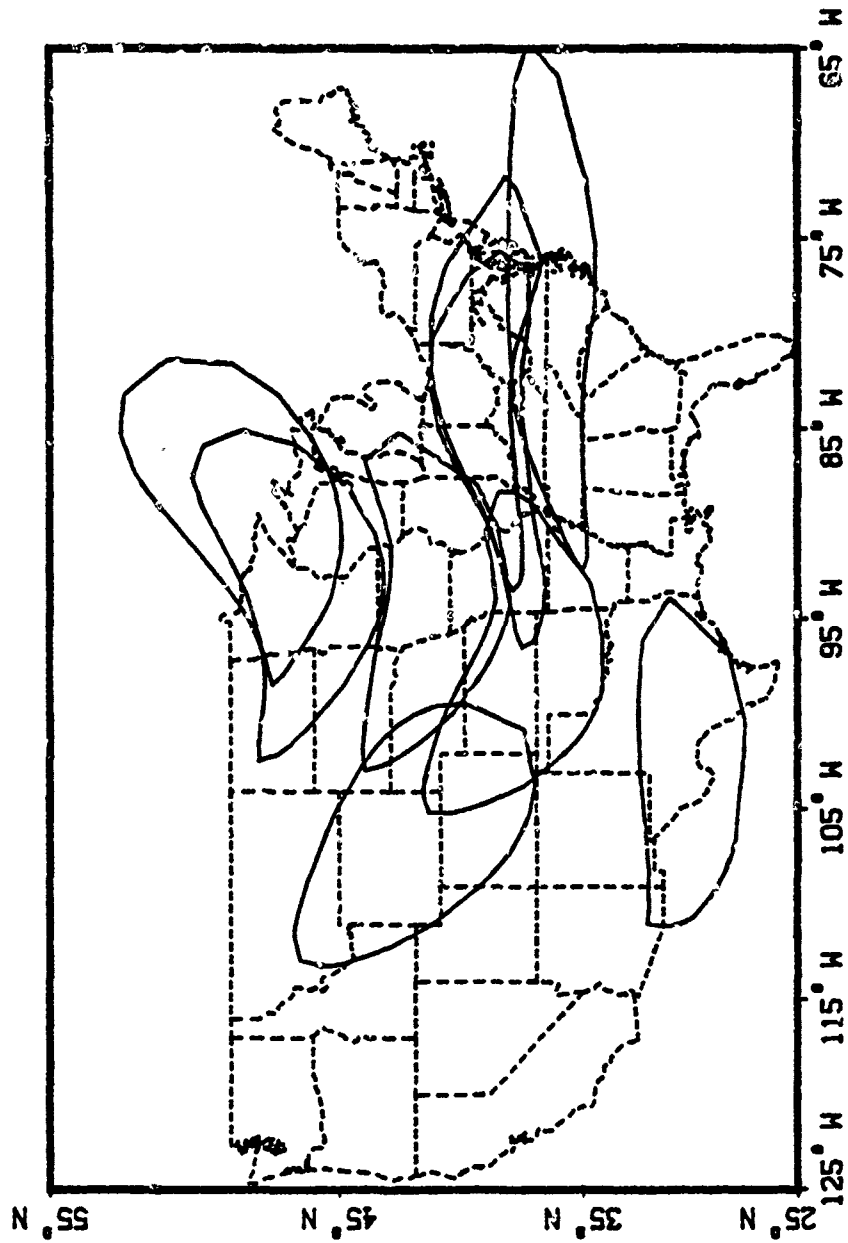

Figure IV-8. Dose Rate Contours

Figure IV-9. Three Dimensional Dose Rate Surface

Summary

A method has been developed to compute fallout dose rate contours around curved hotlines produced by variable winds. The method uses an analytic solution to the dose rate integral Eq (1.1), and hotline coordinates determined with spectral winds (Chapter III). Activity is smeared simultaneously along net crosswind lines as the cloud moves downwind. Dose rate at any arbitrary ground location can be determined, using the technique derived in Appendix F.

V. Validation

Ideally, the new fallout prediction method should be validated by computing fallout dose rate contours for atmospheric nuclear tests, and comparing calculations to actual data and to other model predictions (46)(47)(81). This method requires NMC spectral coefficients to compute the wind vectors that transport falling particles. However, the NMC did not generate and archive the coefficients before 1980. Since the United States conducted atmospheric nuclear testing before 1964, spectral coefficients were not available to validate the fallout transport method with nuclear cloud data.

The NMC Spectral Model was operational when the Mount St. Helens volcano erupted in 1980. Using global wind data for 18, 19, 20 May 80, (116) the NMC generated and provided spectral coefficients to support validation of the new transport method with ash cloud data.

Ash cloud data for the 18 May 80 eruption is extensive; radar observations, fallout collectors, sampling aircraft and satellites provided correlative information for fallout studies. This chapter describes the Mount St. Helens cloud, the transport and deposition data, and calculations of the ashfall hotline location and isomass contours using spectral winds. The excellent agreement between observed and calculated hotline locations and ashfall arrival times confirms that spectral winds can accurately determine trajectories of particles falling from a high yield (megaton-range) cloud.

Further validation is presented for a low yield (kiloton range) cloud. The Defense Nuclear Agency (DNA) detonated 600 tons of high explosives in

New Mexico on 26 October 83. The test explosion, codenamed DIRECT COURSE, created a cloud that rose approximately 3 kilometers above ground, and moved to the northwest. Using spectral coefficients, again supplied by the NMC, the cloud trajectory was computed and compared to observations. Excellent agreement between calculated and observed trajectories confirms that spectral winds can accurately simulate the motion of low yield clouds in the atmosphere.

Following are the Mount St. Helens and DIRECT COURSE cloud analyses. Both cloud studies show that spectral wind transport is a feasible, accurate method for improving fallout modeling with variable winds. The Mount St. Helens analysis was extended to show how the smearing model can be adapted to compute volcanic ashfall and to back-calculate the cloud particle size distribution from ashfall data.

Mount St. Helens Ash Cloud Analysis

Cloud Rise, Transport and Deposition. The eruption of 18 May 80 produced the largest ash cloud of the six major eruptions in 1980 (61). Initiated by a Richter 5.1 earthquake at 0832 Pacific Daylight Time (PDT), Mount St. Helens erupted into a Plinian column of volcanic gases and particles that rose to more than 22 kilometers above ground in approximately 10 minutes (44). Subsequently, the top part of the ash column expanded into a mushroom-shaped cloud that elongated and moved downwind as ash particles fell. The volcano erupted continuously for more than 9 hours.

The ash cloud stabilized at different heights during the nine hour eruption time. Table V-1 shows the approximate altitudes of visible cloud top, bottom and center near stabilization time (90). Time-varying

TABLE V-1

Stabilized Cloud Heights at 0845 PDT (90)

Top	17.1 kilometers
Center	12.1

TABLE V-2

Radar-Detected Cloud Top Heights (44)

<u>Time</u> (PDT)	<u>Height</u>
0915 - 0938	12.0 kilometers
0938 - 1100	12.5
1100 - 1158	14.0
1158 - 1255	13.0
1255 - 1330	12.9
1330 - 1500	13.0
1500 - 1605	13.5
1605 - 1705	15.5

radar observations of cloud top heights are shown in Table V-2. While a visible cloud dimension cannot be related quantitatively to a cloud dimension, the radar-detected cloud top is close to the visible cloud center height. The time-weighted average of radar cloud top heights is 13.3 kilometers above ground level (AGL), ranging from 12.0 to 15.5 kilometers during the eruption.

Satellite data shows that the ash cloud front travelled 500 kilometers in less than 5 hours. Figure V-1 (used here with permission) shows the time-varying position of the satellite-detected cloud's leading edge; the satellite-detected cloud was transported by a high-velocity wind layer centered at approximately 12 kilometers above sea level, ASL. The volcano's mouth was approximately 2.9 kilometers ASL. Figure V-2 shows the initial arrival times of fallout on the ground, along the downwind line of maximum ashfall (the hotline); hotline position was estimated from isomass contours in (90). Cloud transport and deposition are summarized in Figure V-3 (again, used with permission). Ground ashfall generally occurred to the north of the satellite-detected cloud, because wind direction generally veered with increasing height.

Figure V-4 shows the elapsed time of eruption, and times for which the NMC provided spectral coefficients. Most of the 9 hour eruption time was within 6 hours of 00UT 19 May 80, so cloud transport and fallout trajectories were most accurately replicated with persistent winds for that time. Time-varying winds were produced by interpolating spectral winds for different times.

Spectral Winds. The NMC provided 5 sets of spectral coefficients, representing winds from 00UT 18 May 80 through 00UT 20 May 80, at 12 hour

Figure V-1. Satellite-Detected Cloud Outlines (90:579)

Figure V-2. Arrival Time vs Downwind Distance

Figure V-3. Isomass Contours and Satellite Cloud Outlines (90:588)

Figure V-4. Time Line of Eruption and Wind Coefficients

intervals. The coefficients were written on magnetic tape, formatted in 80 column card images (113). One set contains 992 complex pairs for each of two wind vector components at each of 12 levels. There are 23808 complex pairs in each set of coefficients.

Figures V-5 through V-7 show wind vectors computed with the 00UT 19 May 80 coefficients on a $2\frac{1}{2}$ degree latitude/longitude grid over continental United States. The three levels were chosen to illustrate low, middle and high altitude winds in the atmosphere. High altitude tropospheric winds are typically faster than low altitude winds and the flow is generally westerly. Wind vector length is the distance travelled by a parcel of air in 3 hours. The effect of the jet stream is most evident in the 250 millibar wind field, Figure V-6.

Hotline and Isobaric Trajectories. Spectral coefficients were used to compute the ashfall hotline location and isobaric trajectories at ten heights above the volcano. An isobaric trajectory is the path travelled by an air parcel at a fixed height or pressure level. In 1980, isobaric trajectory predictions were used by the United States Geological Survey to forecast ashfall hazards before the volcanic eruption (73)(99).

The hotline locator starts with an initial, stabilized cloud and computes the trajectories of spherical particles falling through variable spectral winds to the ground. The connection of particle landing points on the ground is the hotline. The initial cloud model was a gravity-sorted distribution of particle size vs height, described in Chapter III. The size-height equation was derived from nuclear cloud calculations, so it is weapon yield dependent. In this application, yield is just a parameter for cloud height selection. A range of yields

Figure V-5. 00UT 19 May 80 Wind Field (850 mb)

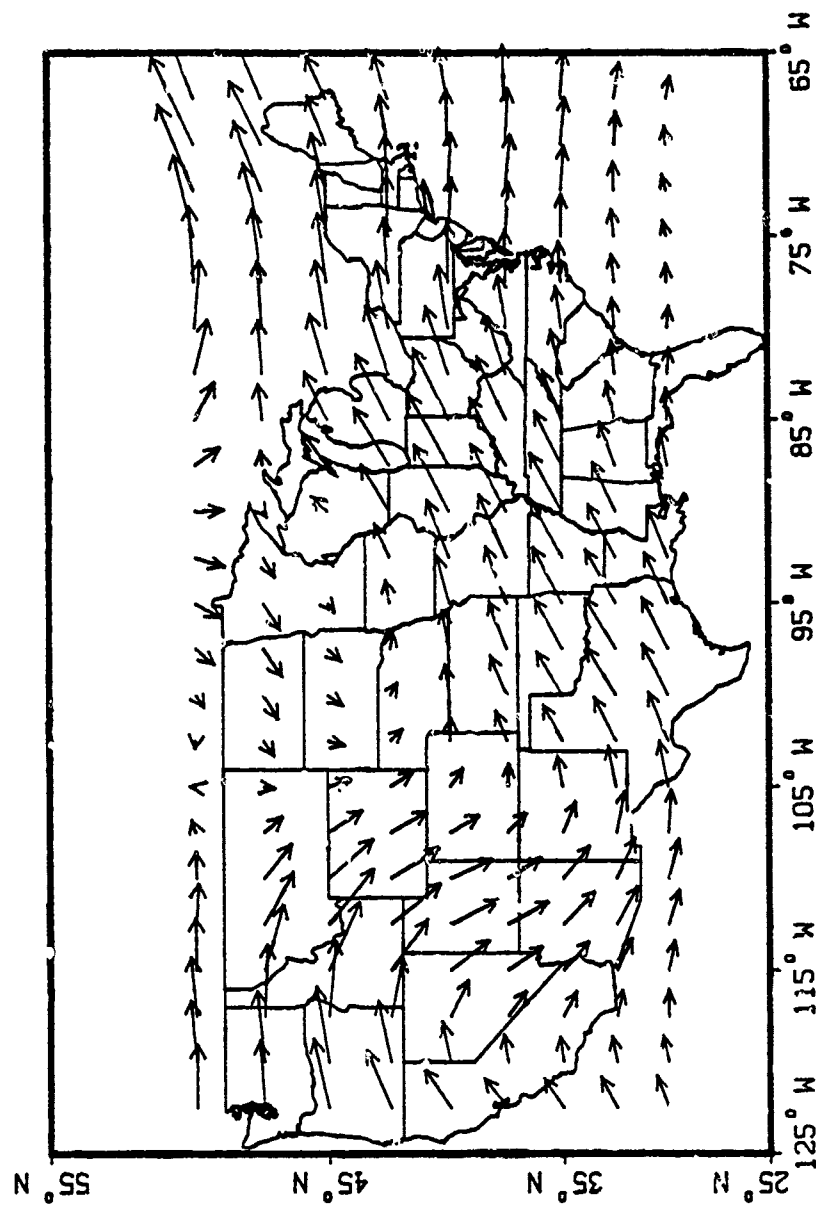

Figure V-6. 00UT 19 May 80 Wind Field (250 mb)

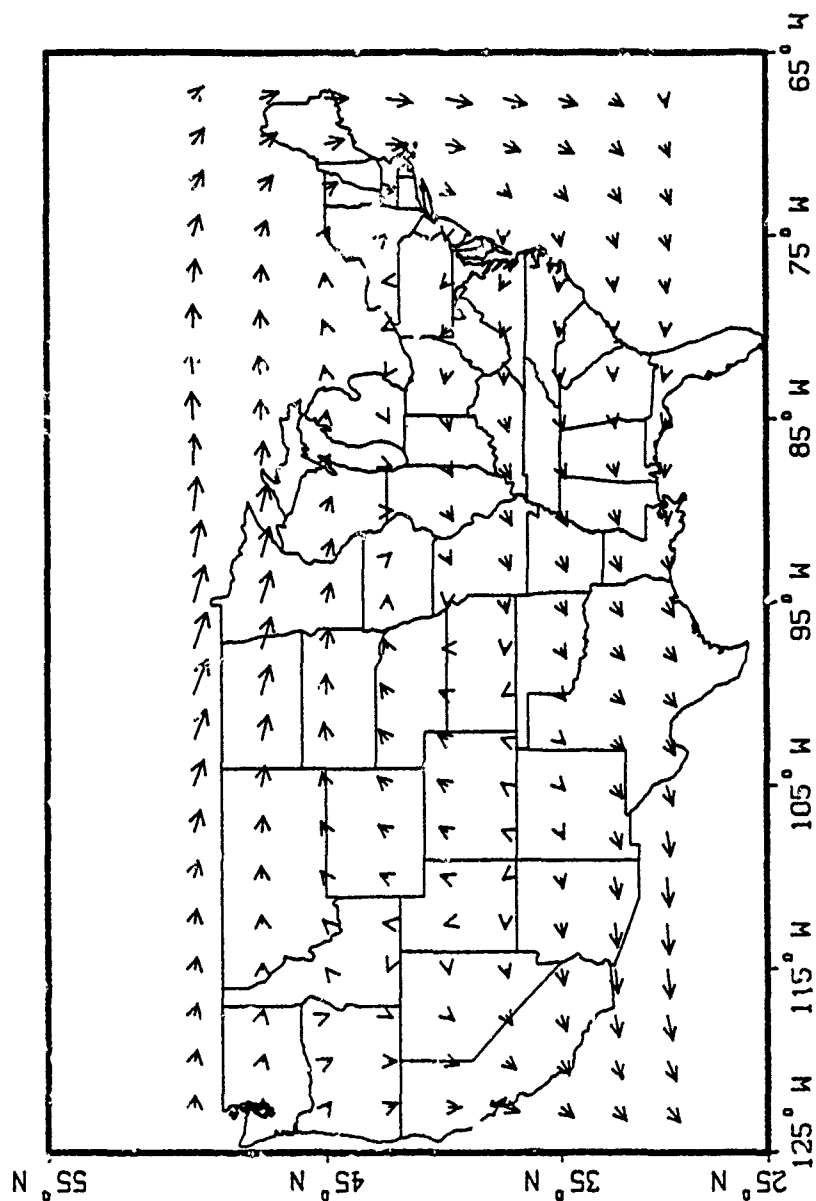

Figure V-7. 00UT 19 May 80 Wind Field (50 mb)

was examined to find a yield that positioned the initial cloud within the altitude bounds detected visually and with radar, matching the observed hotline location. Figure V-8 shows how the computed hotline location varied with different choices of the yield parameter in the 0000T 19 May 80 winds. The hotline from a 0.5 megaton initial cloud closely matched the actual hotline, although all three of the predicted hotlines in Figure V-8 have generally correct position and curvature. The 0.5 megaton yield is not an estimate of eruption energy; yield is a parameter used to position the initial cloud. Total eruption energy has been estimated to be much higher, approximately 24 megatons (61:563).

Furthermore, computed arrival times of volcanic ash particles agreed with the observed ashfall onset times (38). Figure V-9 shows observed and calculated arrival times on the hotline out to 1000 kilometers from the volcano. Arrival time is an excellent indicator of the suitability of spectral winds for fallout calculations, because arrival time incorporates all wind vectors computed along each particle's trajectory. Also, arrival times are computed during hotline location (Chapter III), and used to define the net wind vectors in the variable wind smearing model (Chapter IV). The root-mean-square (rms) difference between observed and computed net wind speeds is 2.1 meters per second. Figure V-9 also shows the arrival times computed with the same initial cloud, using a constant vertical wind profile for transport calculations. The constant vertical wind profile is a combination of linear regression fits to wind measurements at Salem, Oregon, at 3 different times (21). The constant wind profile generally overpredicts arrival times; the rms difference between observed and computed net wind speeds is 4.3 meters

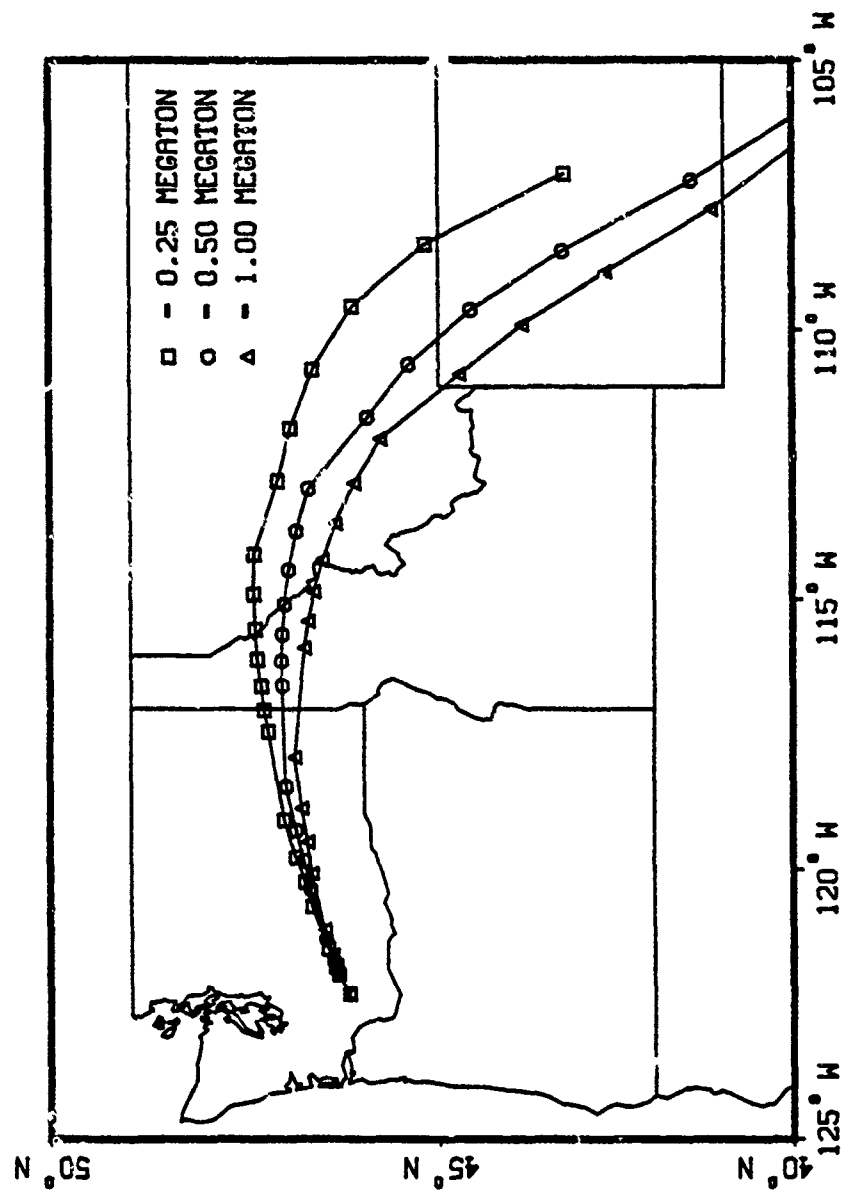

Figure V-8. Hotlines: Yield Variations

Figure V-9. Arrival Time Data and Calculations

per second. The spectral wind field produced net wind vectors that were twice as accurate as the net wind vectors computed with a constant vertical profile.

With spectral winds for different times, the predicted hotlines diverged significantly. Figure V-10 shows hotlines predicted with spectral coefficients for four different times. All preceding calculations were done with one set of spectral coefficients; winds were spatially, not temporally, interpolated. The same three dimensional wind field persisted during cloud transport. As expected, the 0000 19 May 80 winds most accurately replicated the observed hotline.

Temporal variations were modeled by interpolating spectral coefficients or wind vectors for adjacent times as particles fell from the initial cloud. Knowing when a particle starts to fall, the temporally adjacent coefficient sets can be identified and interpolated to compute winds at any time during particle fall. Figure V-11 shows hotlines computed with temporally varying spectral winds, using three different starting times: 0845, 1145 and 1445 PDT. The three curves on Figure V-11 show how temporal changes in trajectory winds affected hotline placement. Within 300 kilometers of the volcano, temporal wind variations during the eruption did not significantly affect ashfall location. However, at longer ranges and longer travel times, the effects of temporal wind changes are apparent. Ash that erupted in the first six hours curved southward sooner than ash that erupted later, causing the ashfall to be smeared over wider areas at long distances. Temporally varying winds could be used to predict ash trajectories if the time-varying eruption rate data could be estimated from radar measurements (44)(45).

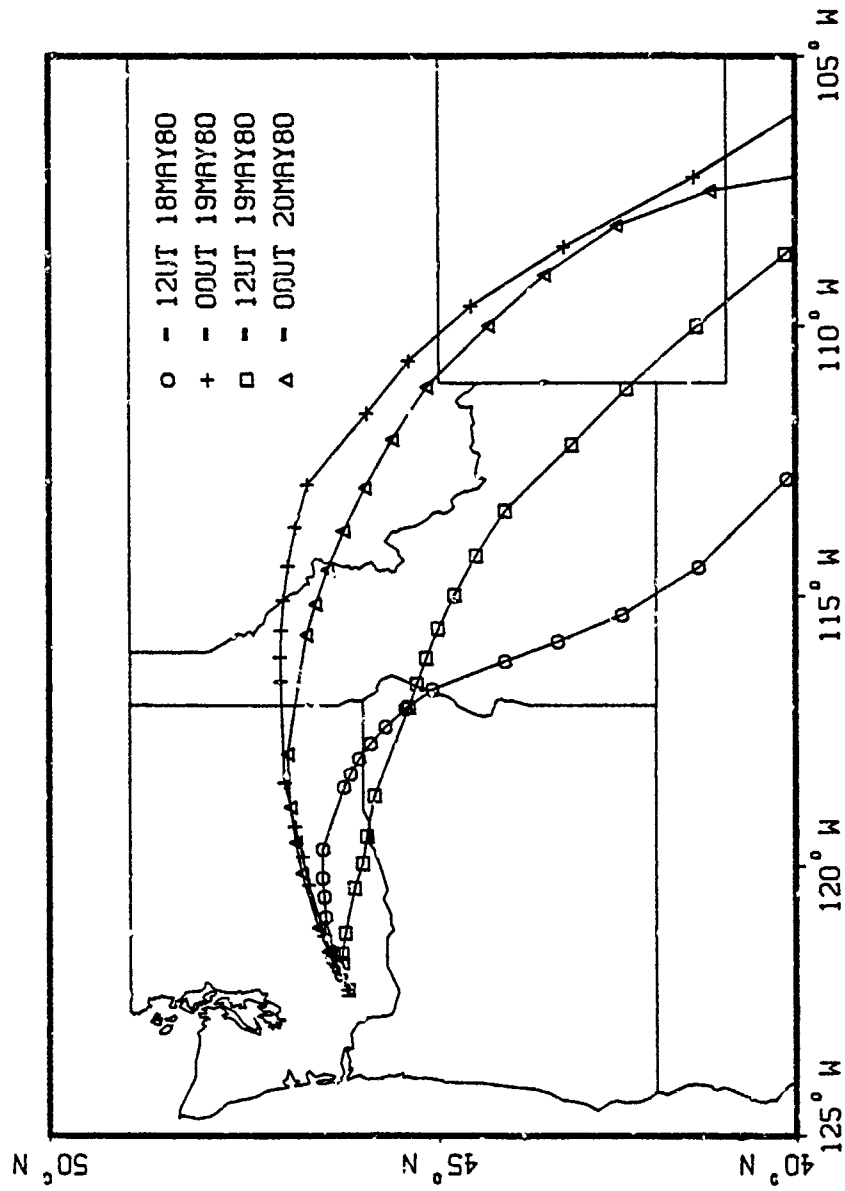

Figure V-10. Hotlines: Four Different Times

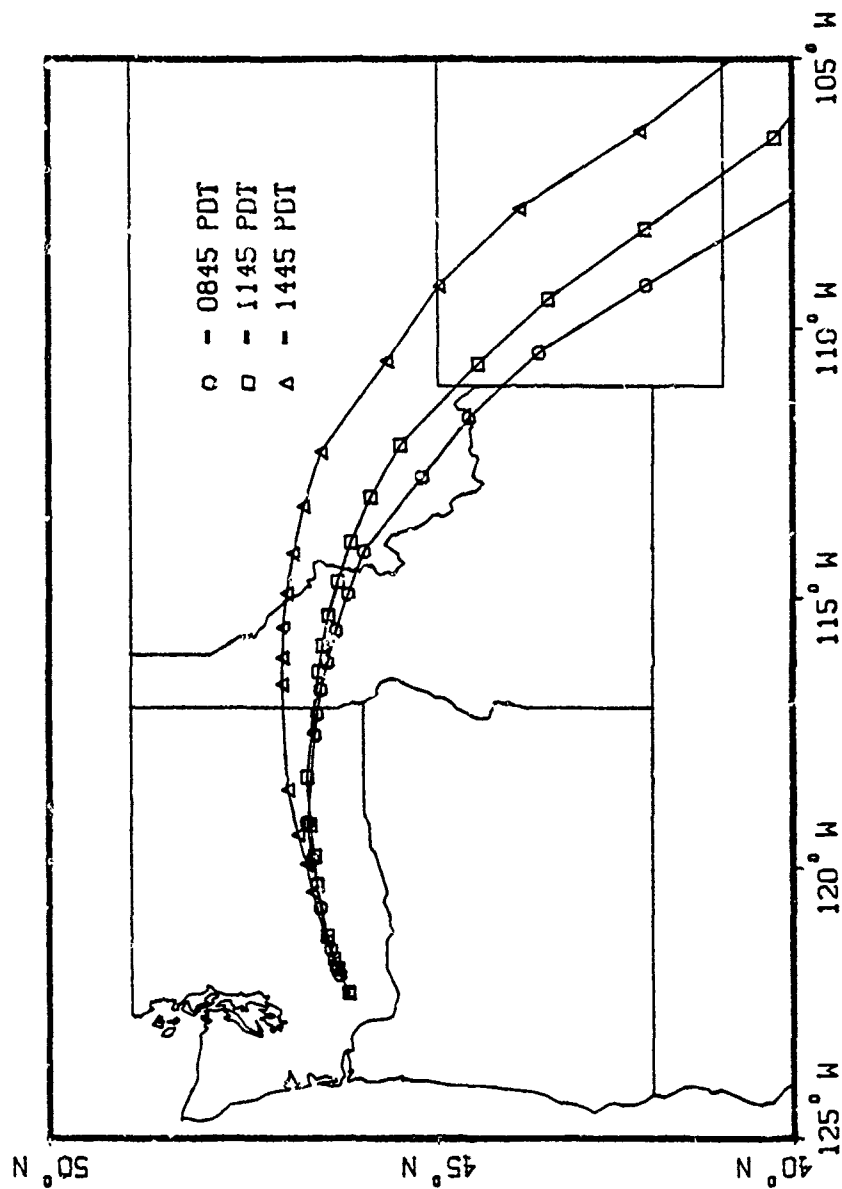

Figure V-11. Hotlines: Three Different Starting Times in Variable Winds

Small volcanic ash particles, ≤ 1 micrometer in diameter remained suspended in the atmosphere for a long time. Aircraft measurements showed that Mount St. Helens ash actually circled the earth in about 16 days (21). Long range transport was computed with temporally varying spectral winds in constant-altitude trajectories. In this report, constant-altitude trajectories are also isobaric, because the U.S. Standard Atmosphere was used for all atmosphere state parameter calculations. Isobaric trajectories simulate the transport of particles with negligible fall speeds. Figures V-12 and V-13 show isobaric trajectories near the volcano and over a continental scale, computed with temporally interpolated spectral winds, starting at 0845 on 18 May 80. Two general paths are evident: (1) the upper tropospheric winds moved particles southeastward over Wyoming and Kansas before turning to the northeast; (2) the low level winds carried ash northeastward into Canada. The National Oceanic and Atmospheric Administration (NOAA) predicted isobaric ash trajectories using measured and forecasted wind data (26)(101). The NOAA predictions are shown in Figure V-14. The same two general paths are also evident in the NOAA predictions.

Ash Fallout Model. The dose rate equation, Eq (4.1), was modified to compute mass of volcanic ash per unit area on the ground. Three changes were necessary to derive an ashfall equation.

First, the source normalization constant, k , weapon yield, Y , and fission fraction, ff , were replaced by the mass lofted into the volcanic cloud. Mass of downwind ash was approximately 5×10^{14} grams (44)(90). Estimates of total mass assumed rock mass densities of 2.0 to 2.8 grams per cubic centimeter, representative of the solid, unfractured rock on

Figure V-12. Isobaric Trajectories with Temporally Varying Winds

Figure V-13. Isobaric Trajectories with Temporally Varying Winds

Figure V-14. NOAA Isobaric Trajectories

the mountain (39). However, measurements of ash particles' mass density showed many particles with density less than 2.0 grams per cubic centimeter (21). Cloud particles can have various mass densities, due to different rock types and because the particles can contain air pockets and fissures produced during solidification, collision with other particles and breakage during eruption (118). In this report, 2.0 grams per cubic centimeter was used as a representative value. In fact, hotline location was not particularly sensitive to density variation; see Figure V-15.

Second, the fractionated activity-size frequency distribution, $A(r)$, was replaced by a particle mass-size distribution function for the ash cloud. A cloud distribution was measured by Carey and Sigurdsson (21) using fallout samples; a cumulative form of their histogram is shown in Figure V-16, with the DELFIC default mass-size spectrum for reference. The measured distribution suggests that the Mount St. Helens ash cloud size distribution was multimodal. A multimodal size distribution is consistent with qualitative and quantitative analyses of ash fallout (16). Observed ash was a mixture of two distinctly different rock types: old rocks from previous eruptions and new magma (21)(39)(91). The measured particle mass-size frequency histogram was fit with an analytic function using the nine parameter function minimization technique described in Appendix G. Following is a trimodal log-normal function that fits the histogram:

$$M(r) = \sum_{i=1}^3 \frac{f_i}{\sqrt{2\pi} \beta_i r} \text{EXP} \left(-\frac{1}{2} \left(\frac{\ln r - \alpha_i}{\beta_i} \right)^2 \right) \quad (5.1)$$

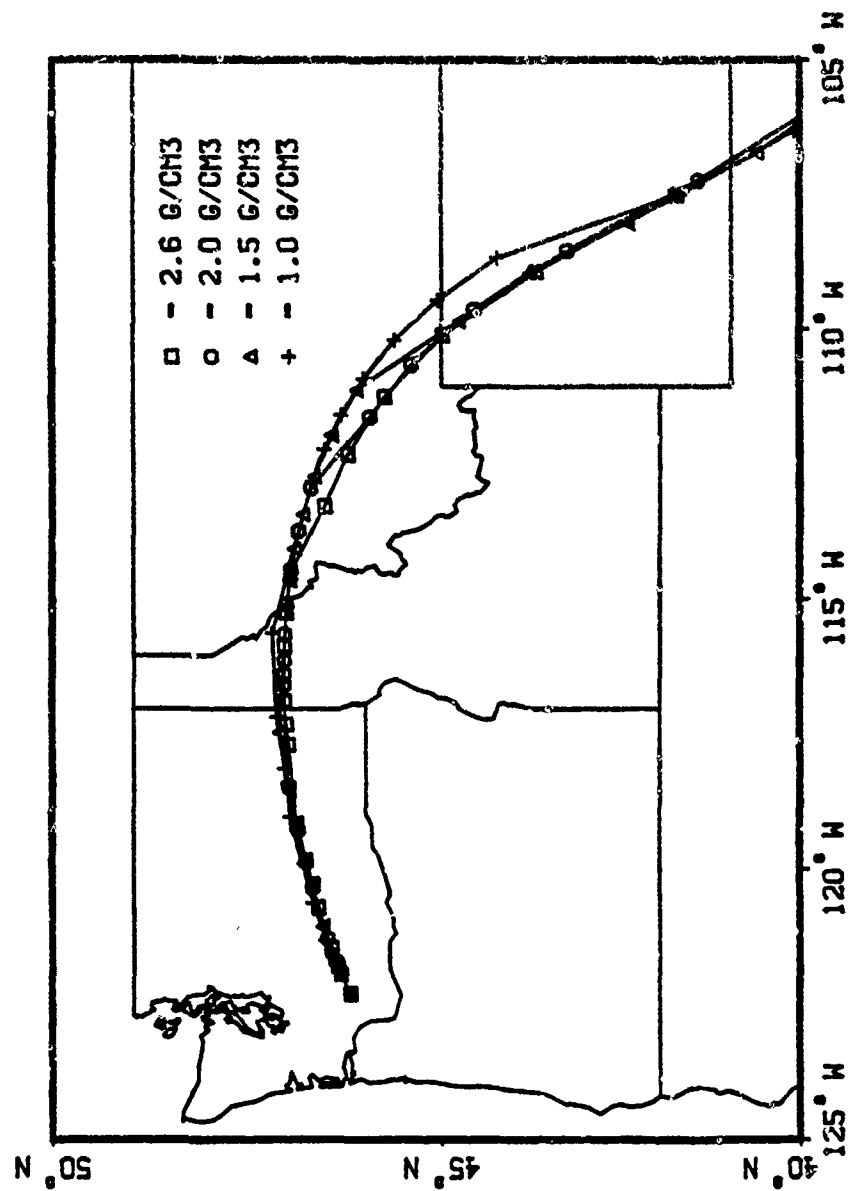

Figure V-15. Hotlines: Particle Density Variations

Figure V-16. Measured Histogram and Nuclear Particle Size Distribution

where

$M(r)$ = particle mass-size frequency distribution function

f_i = fraction of $M(r)$ composed of the i -th distribution

β_i = log-slope

$\alpha_i = \ln(r_{50}^i)$

r_{50}^i = median particle radius in the i -th distribution

See Table V-3 for numerical values of distribution parameters. Log-normal functions were selected because explosive processes often produce log-normal particle size spectra (2)(40) and because aircraft measurements of the ash cloud showed log-normal distributions (36). Figures V-17 and 18 show the log-normal fit and the ash cloud histogram. Three radius modes occur near 8, 60 and 250 micrometers.

The third change to the dose rate equation necessary to derive an ashfall equation is to replace yield-dependent expressions for lateral deviations with empirical expressions for ash cloud spreading. The satellite-detected ash cloud expanded with time as follows (21):

$$w = 0.006 t \quad (5.2)$$

where

w = width of plume front (kilometers)

t = elapsed time since start of eruption (seconds)

Define
$$\sigma = (\sigma_x^2 + \sigma_y^2)^{\frac{1}{2}} \quad (5.3)$$

and
$$(\sigma_x, \sigma_y) = \frac{(V_x, V_y)}{(\dot{V}_x^2 + \dot{V}_y^2)^{\frac{1}{2}}} \sigma \quad (5.4)$$

Assume that
$$w \approx 4 \sigma \quad (5.5)$$

So,
$$\sigma = 0.0015 t \quad (5.6)$$

TABLE V-3

Trimodal Log-Normal Function Parameters
for the Measured Particle Sizes

i	α_i	β_i	f_i
1	2.031	0.852	0.66
2	4.176	0.633	0.25
3	5.495	0.445	0.09

Figure V-17. Fit to Measured Size Distribution

Figure V-18. Fit to Measured Size Distribution (Cumulative)

The preceding three changes convert the dose rate equation into an ashfall equation:

$$A = \frac{T M(r) |dr/dt|}{\sqrt{2\pi} \sigma_V} \text{EXP} \left(-\frac{1}{2} \left(\frac{x V_y - y V_x}{\sigma_V} \right)^2 \right) \quad (5.7)$$

where

A = ash mass/area on the ground at (x,y)
T = total ash mass lofted into initial cloud during eruption
M(r) = particle mass-size frequency distribution

Figure V-19 shows isomass contours computed with Eq (5.7) using hotline coordinates of Figure V-8. On the hotline, computed mass decreased with increasing distance from the volcano. Figure V-20 shows computed ashfall on the hotline, compared to actual measurements. The fallout data indicates a secondary maximum at approximately 325 kilometers downwind, near Ritzville, Washington. Figure V-3 also shows the "Ritzville Bulge". The Ritzville bulge was not predicted using the measured particle size distribution (Table V-3) in the ashfall equation Eq (5.7).

Particle Sizes in the Falling Cloud. The measured grain size distribution represents the size spectrum of fallen, not falling, particles. The falling cloud particle size spectrum contained aggregates of smaller particles; many of the larger, falling particles were broken during impact and during the mechanical sieving processes used to size the ash samples. Some falling ash clusters were captured and sized without breakage, near Pullman, Washington; data indicates that falling particles were two to five times larger than fallout particle sizes reported for that location (52)(100). The unbroken particle data is consistent with terminal

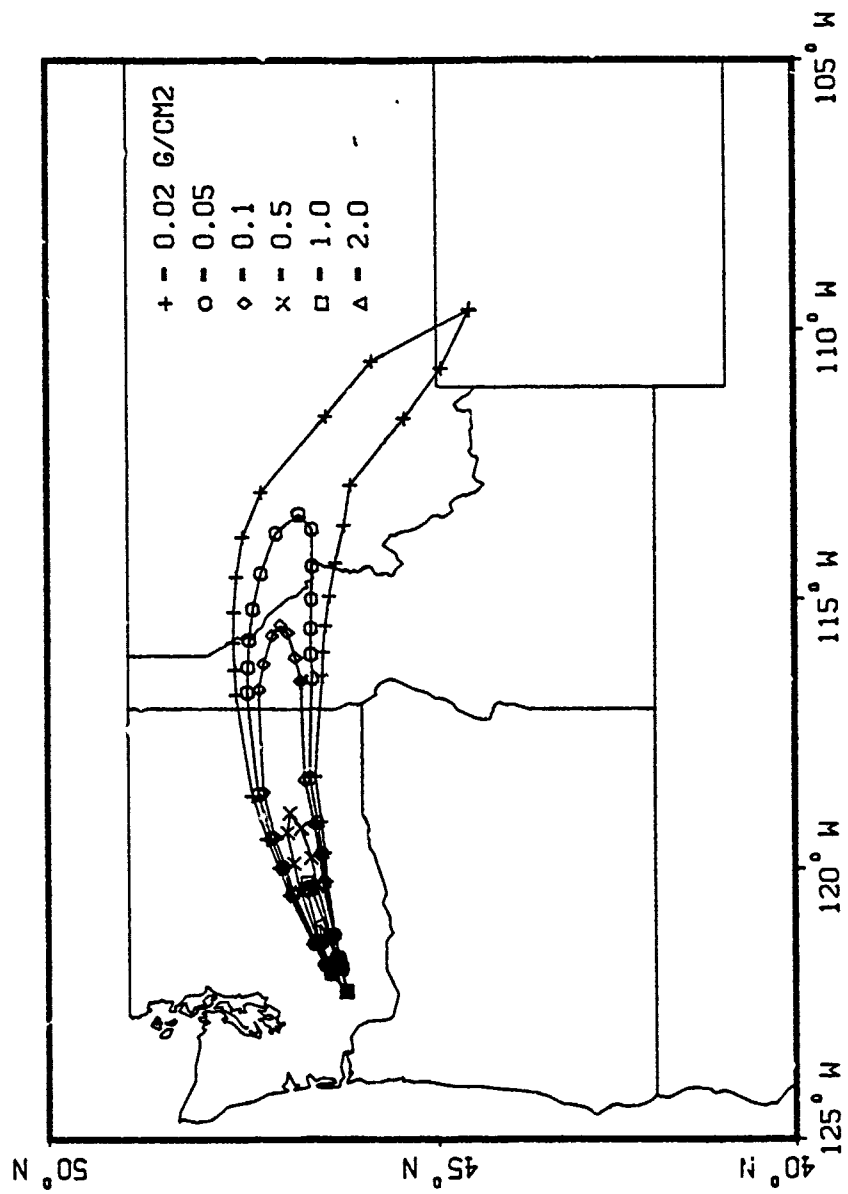

Figure V-19. Isomass Contours

Figure V-20. Isomass on Hotline

velocity calculations. Figure V-21 shows where theoretical fall calculations predict that particles of various sizes and densities would land. Computed sizes are consistently larger than measured sizes landing at the same place.

Using Eq (5.7), the actual ashfall data and the function minimization technique (Appendix G), a particle mass-size frequency spectrum was back-calculated for the falling cloud. Specifically, a size distribution function, $M'(r)$, was found that enables the ashfall equation to closely match the ashfall data, including the Ritzville bulge (90). Table V-4 shows the parameters for $M'(r)$; the function is plotted in Figures V-22 and V-23. The size spectrum has a mode near 60 μm and particles smaller than 10 μm constitute less than 10% of the falling cloud mass, compared to 40% of the measured fallout mass. It is interesting to note, however, that the measured size distribution (Figure V-17) also contains a mode near 60 μm . The presence of that 60 μm secondary mode in the measured size distribution could be an artifact of its parent, falling cloud distribution, diminished by the particle breakage that produced the dominant measured mode near 8 μm .

The back-calculated cloud particle size spectrum was used in Eq (5.7) to compute ash mass on and around the hotline. Figure V-24 shows the hotline mass compared to measured data; the Ritzville bulge is accurately replicated. Isomass contours in Figure V-25 also show the Ritzville bulge with appropriate widening of the 1.0 gram per square centimeter contour around Ritzville.

At distances beyond 500 kilometers from the volcano, contours computed from spectral winds are slightly east of the contours extrapolated

from fallout and satellite data (see Figure V-3). Ashfall data from South Dakota strongly suggests that the extrapolated data contours in Figure V-3 are not accurately positioned (28). In fact, the computed contours in Figure V-25 may better represent the actual ashfall locations at those long ranges.

Summary. Using spectral winds for particle transport, the Mount St. Helens ashfall hotline was accurately computed, using a gravity-sorted initial cloud located at approximately 12 kilometers AGL. Spectral winds also produced long range isobaric trajectories that agreed with NOAA predictions of ash transport over the United States and Canada. Computed fallout arrival times agreed with eyewitness accounts. An ashfall equation was derived to predict volcanic ash mass at downwind points. The measured fallout mass-size frequency distribution cannot produce the Ritzville bulge in fallout calculations. A particle size distribution was determined for the falling cloud, using the ashfall equation and ashfall data. The computed falling cloud spectrum simulates the Ritzville bulge and suggests that a secondary mode in the measured distribution is an artifact of the falling cloud's mass-size frequency distribution. Figures V-26 and V-27 show isomass surfaces in three dimensions, computed with the falling and fallen particle size distributions, respectively. Each plot displays 5000 values determined at surface positions that are nodes of a Cartesian grid, with four kilometer spacing laterally. The method derived in Appendix F was used to find the hotline points associated with each of the 5000 surface positions. The vertical axis is the natural logarithm of ash mass, normalized to the peak value near the volcano, and truncated at 1.0% of the peak value.

DIRECT COURSE High Explosive Cloud Analysis

Description of Test Event. A six hundred ton sphere of high explosives was detonated on 26 October 83 at the White Sands Missile Range. The explosives were suspended from a fiberglass and steel tower, approximately fifty meters above ground level (AGL) to simulate a weapon airburst. The explosion produced a particle cloud containing explosive by-products, dirt and tower debris that rose to approximately 3000 meters AGL as it was transported to the northwest by prevailing winds. Climatologically, winds are westerly, so DNA's debris (not radioactive) fallout collection experiments had been positioned to the east of ground zero before the test. No debris fallout data was obtained. However, DNA tracked the cloud with cameras and with a sampling aircraft, so the cloud motion data could be used to validate the spectral wind transport model.

This test is a good validation exercise for spectral wind transport. The relatively low cloud simulated a cloud from a kiloton range nuclear burst. The coefficients are least accurate in the lower part of the atmosphere due to terrain and boundary layer shear effects. Furthermore, the cloud was tracked for distances less than the spacing between most wind observation sites used to generate the spectral coefficients. Thus, it was theoretically possible for cloud transport to be affected by atmospheric disturbances too small to appear in the spectral model.

Spectral Winds. The NMC provided two sets of spectral coefficients: 12UT 26 Oct 83 and 00UT 27 Oct 83. The explosion occurred at 18UT 26 Oct 83. The coefficients were written on magnetic tape (114) in the same format as those provided for the Mount St. Helens analysis. Figures

V-28 through V-31 show spectral winds over the United States computed at the lowest four levels above ground for 00UT 27 Oct 83. Easterly flow over New Mexico is apparently caused by a strong low pressure system located over Northern Mexico. Figure V-32 shows wind speed vs altitude computed with coefficients and measured at the test site (22). The spectral winds lack the vertical resolution of radiosonde data and they do not model shear in the lowest layer of atmosphere. However, because the cloud transport was dominated by stronger winds at high altitudes, the spectral winds did model the westward motion of the cloud.

Cloud Motion. Isobaric trajectories are shown in Figures V-33 and V-34 for both sets of spectral coefficients. Figure V-35 shows isobaric trajectories using a new coefficient set, derived by linearly interpolating the 12UT and 00UT coefficients to represent winds at 18UT 26 Oct 83. The aircraft position data illustrates where the sampling aircraft was located when the pilot reported that he was in any part of the cloud or stem (23). Table V-5 shows the aircraft position data, including altitudes. Spectral winds most accurately modeled cloud transport near the cloud top (500 millibars). The spectral model clearly simulated the unusual easterly flow that dominated transport of the DIRECT COURSE cloud.

Summary. The DIRECT COURSE cloud was transported to the northwest by climatologically atypical winds (13)(14). Spectral winds predicted isobaric trajectories correctly, to the northwest. The cloud trajectory and spectral wind trajectory agree best near the top of the 3 kilometer high cloud. The low altitude spectral winds did not model the strong vertical shear in the 850 to 700 millibar level.

VI. Error Analysis

Errors in the net wind components V_x and V_y were shown in Chapter V. They were determined by comparing the computed and actual arrival times of fallout from the Mount St. Helens ash cloud. The computed rms error of 2.1 meters per second in the net wind was even less than the average error of 5.0 meters per second in spectral wind vectors (Chapter II). This chapter addresses how uncertainties in the spectral winds contribute to error in computed dose rate.

Sources of Error

The error in a dose rate calculation is influenced by uncertainties in the independent variables of the dose rate equation, Eq (4.1). Standard deviations of several variables are listed in Table VI-1; deviations were based on the ranges of published values. Table VI-1 also shows best estimates of the variables used in this analysis.

Error Propagation Formula

An error propagation formula for the dose rate equation was derived by assuming that errors are symmetric about zero, and that errors in any two independent variables are uncorrelated (10).

$$\begin{aligned}\sigma_D^2 \approx & \sigma_k^2 \left(\frac{\partial \dot{D}}{\partial k}\right)^2 + \sigma_Y^2 \left(\frac{\partial \dot{D}}{\partial Y}\right)^2 + \sigma_{ff}^2 \left(\frac{\partial \dot{D}}{\partial ff}\right)^2 + \sigma_{fv}^2 \left(\frac{\partial \dot{D}}{\partial fv}\right)^2 \\ & + \sigma_{\alpha_0}^2 \left(\frac{\partial \dot{D}}{\partial \alpha_0}\right)^2 + \sigma_{\beta_3}^2 \left(\frac{\partial \dot{D}}{\partial \beta_3}\right)^2 + \sigma_{\beta_2}^2 \left(\frac{\partial \dot{D}}{\partial \beta_2}\right)^2 + \sigma_{S_x}^2 \left(\frac{\partial \dot{D}}{\partial S_x}\right)^2 \\ & + \sigma_{S_y}^2 \left(\frac{\partial \dot{D}}{\partial S_y}\right)^2 + \sigma_{V_x}^2 \left(\frac{\partial \dot{D}}{\partial V_x}\right)^2 + \sigma_{V_y}^2 \left(\frac{\partial \dot{D}}{\partial V_y}\right)^2\end{aligned}\quad (6.1)$$

TABLE VI-1

Nominal Values and Standard Deviations
of Variables in Dose Rate Equations

(S_x, S_y), wind shear components	computed with spectral winds	50% of (S_x, S_y)	estimate
Y, weapon yield	1 megaton used for this analysis	0.1	estimate

The error propagation formula Eq (6.1) describes how errors may propagate from independent variables into a dose rate error. Generally, the variances are squares of the deviations estimated from published uncertainty bounds. Analytic expressions for partial derivatives were obtained by differentiating the dose rate equation with respect to each independent variable. The dose rate equation depends on net wind explicitly in the spatial distribution term and implicitly in the arrival rate term.

Dose Rate Error

A hypothetical megaton burst was studied to quantify the error in dose rate caused by uncertainties in the independent variables. Table VI-2 shows the relative and absolute magnitudes of wind component errors that contribute to dose rate errors. Values are averages for ten ground points located on the 200 Roentgen contour. The 200 Roentgen exposure contour was chosen because 200 Roentgens produce approximately 200 rems dose to the surface of a human body from .3 to 3 MeV gamma rays. A 200 rem dose is the threshold for radiation sickness, based on data from Hiroshima and Nagasaki (41). Average dose rate on the contour is 42.3 R/hr at one hour after burst.

Spectral wind uncertainties contribute minimally to the error in computed dose rate. About 4% of the dose rate variance can be attributed to wind uncertainty when spectral coefficients are used for particle transport calculations. This analysis assumed that the deviation in net wind components was 5 meters per second. The net wind vectors computed in the Mount St. Helens analysis diverged from actual data by approximately 2 meters per second. Therefore, a spectral wind component

TABLE VI-2

Wind Error Contributions

		$u = V_x$	$u = V_y$
Dose Rate Error	$\sigma_u \left(\frac{\partial \dot{D}}{\partial u} \right)$	33.	30.
Relative Error	$\frac{\sigma_u \left(\frac{\partial \dot{D}}{\partial u} \right)}{\dot{D}}$	0.80	0.74
Fraction of Dose Rate Variance	$\frac{\sigma_u^2 \left(\frac{\partial \dot{D}}{\partial u} \right)^2}{\sigma_{\dot{D}}^2}$	0.043	0.039

may contribute even less than 4% of the dose rate variance.

The relative errors are consistent with similar error estimates determined by W. Slinn in his assessment of meteorological uncertainties affecting the Nuclear Regulatory Commission Reactor Safety Study (98). Slinn estimates that the relative error in radionuclide concentrations downwind of an accidental reactor release, due to wind speed uncertainties, is approximately 50% of the mean concentration. This error analysis indicated that wind-induced dose rate errors are 80% (maximum) of the mean dose rate.

VII. Summary, Conclusions and Recommendations

This chapter summarizes the analyses, findings and conclusions of this research. In general, the study demonstrated the feasibility of using spectral coefficients to compute fallout particle transport anywhere in the atmosphere. Spectral winds will improve state-of-the-art fallout modeling by accounting for wind variability effects on cloud trajectories. This new technique was validated by matching a volcanic ash cloud hotline and a high explosive cloud trajectory. Wind errors were actually quantified by comparing observed and calculated particle arrival times from the volcanic ash cloud.

Particle Transport with Spectral Winds

The NMC spectral coefficients were used with truncated orthogonal polynomials to compute wind vectors along trajectories of falling particles. Computed winds were linearly interpolated between the discrete spectral heights and between sequential times. Particle trajectories were smooth and continuous in all dimensions. Reducing the truncation limit to fewer than 30 waves significantly altered winds with speeds less than 1 meter per second. This study used data derived from radio-sonde fits; forecasted coefficients could be used to predict fallout transport if real time data is not available (e.g. post-attack).

Variable Wind Smearing Model

Variable winds produced realistically curved hotlines, so a smearing code was developed that incorporated the two-step method to determine dose rate at a point.

Hotline Location. A hotline locator model was constructed, using spectral winds to transport an array of trace particles falling from the initial cloud to the ground. The hotline was defined as the piecewise linear connection of particle landing points on the ground. The initial cloud was a correlation of DELFIC's gravity-sorted particle wafer heights. Sample hotlines were computed for several locations. Wind shear was also computed with spectral winds along each particle's trajectory.

Dose Rate Calculation. A fallout smearing model was developed for use with curved hotline coordinates that were generated by the hotline locator and spectral winds. The model determines the coordinates of any specified dose rate contour around a hotline. A technique was devised to compute dose rate at arbitrary points downwind of the burst. The two dimensional lateral spread of cloud activity is simulated with a bi-directional Gaussian function, normalized in the net crosswind direction. The dose rate equation for variable winds reduces to the constant wind equation when a constant unidirectional wind vector is assumed for cloud transport.

Mount St. Helens Analysis

Ash cloud data from the 18 May 80 eruption of the Mount St. Helens volcano was used to validate the new fallout transport method. With an initial cloud that was positioned within the observed heights of the stabilized eruption plume, the ashfall hotline location was computed with spectral coefficients provided by the NMC. The computed hotline location accurately replicated the actual fallout hotline and correctly

curved to the southeast through Idaho and Wyoming. Hotline position was not sensitive to particle density. Computed arrival times of volcanic ash at points on the ground were compared to observations, this comparison provided an excellent quantification of the uncertainty in the net wind vector computed with spectral winds.

Hotline calculations with spectral coefficients for four different times showed that particle transport was dominated by winds reported for 00UT 19 May 80. Temporally varying spectral winds were computed by interpolating spectral winds. Those calculations showed that part of the plume's lateral spread was caused by time-varying winds during the nine hour eruption. Isobaric trajectory calculations with spectral winds also agreed with published data, showing low altitude ash going eastward over Canada and high altitude ash over the United States.

A volcanic ashfall equation was derived from the dose rate equation. Mass per unit area of volcanic ash was computed along the hotline, and isomass contours were determined using a measured ash particle size distribution. Computed contours were similar to fallout data, but they did not replicate the Ritzville bulge. Using the ashfall data, a particle size distribution was back-calculated that did reproduce the mass bulge in isomass contours and on the hotline. The back-calculated distribution had a single mode near 60 μm ; the measured distribution was trimodal, with modes near 8, 60 and 250 μm . The 60 μm mode in the measured distribution may be an artifact of the actual falling cloud's size spectrum, before collision, impact and mechanical sieving broke the aggregate, clustered particles into smaller, constituent pieces. By analogy, particle breakup may also have happened in nuclear fallout

particle measurements, especially in Pacific tests where large amounts of water were entrained into the cloud, facilitating aggregation of small particles into larger clusters.

DIRECT COURSE Analysis

The actual cloud trajectory was determined from visual and aircraft tracking data. Isobaric trajectories were computed with two sets of spectral coefficients supplied by the NMC. Spectral winds correctly specified the northwestward cloud motion. However, comparisons of actual wind profiles with spectral wind profiles demonstrated that spectral winds, as expected, lack vertical resolution and shear between the lowest spectral height and the ground. Accordingly, the spectral winds more accurately replicated the trajectory of the top half of the high explosive cloud than the bottom half. Particle transport with spectral winds should be most accurate when the initial cloud is so high that the earth's boundary layer is a small part of the particles' trajectories.

Error Analysis

An error propagation formula was used to quantify the effects of wind (and other variables') uncertainties on computed dose rate. Wind component uncertainties contributed approximately 4% of the variance in dose rate, assuming ± 5 meters per second for the net wind uncertainty, based on errors in spectral wind vectors. The Mount St. Helens data suggests that the net wind uncertainty is actually closer to ± 2 meters per second, so wind contributions to dose rate error may be much less than 4% of the dose rate variance.

Recommendations

1. Use forecast coefficients to determine how far in advance trajectories can be accurately predicted. This study used coefficients for winds at data observation times. The NMC can derive forecast coefficients using a global circulation model.

2. Modify DELFIC to use spectral winds. However, realistically variable winds may exacerbate the numerical break-up problem previously observed with DELFIC at long ranges. Wafers may become widely separated in variable winds.

3. Develop a set of spectral coefficients from archived wind data for six nuclear tests. The nuclear tests should be the same ones previously used to benchmark DELFIC, WSEG, and DNAF-1 fallout codes. (Test Event Codenames: Johnie Boy, Jangle-S, Small Boy, Koon, Zuni, and Bravo) Use the coefficients and fallout data to further validate the spectral wind transport method.

4. Develop a particle aggregation model, accounting for the key processes that promote aggregation in particle clouds.

5. In future volcanic ash fallout experiments, measure the falling particle size distribution, using nondestructive techniques, such as cameras and laser spectrometers, to discriminate between falling and fallen particle size spectra.

Appendix A

Spectral Coefficients

Table A-1 contains some spectral coefficients for the westerly wind component on 00UT 16 Jan 82. There are three complex pairs per line, format (6E13.7). The coefficients are listed for the first two zonal wave numbers ($\ell = 0$ and 1). The imaginary parts are zero when $\ell = 0$, because only the real part of the summation is used to compute wind speed, and the spherical harmonics are real when $\ell = 0$; see Eq (2.3).

Appendix B

Derivation of Spectral Wind Equations

Wind vector components at a fixed height in the atmosphere are correlated in space with the following expansion:

$$(U, V) = (u, v) \cos \phi = \sum_{\ell=-J}^J \sum_{n=|\ell|}^{|\ell|+J+1} (U_n^\ell, V_n^\ell) P_n^\ell(\sin \phi) \text{EXP}(i\ell\lambda) \quad (\text{B.1})$$

Terms are defined in Chapter II.

The ℓ -summation in Eq (B.1) can be expressed as follows:

$$\sum_{\ell=-J}^J = \sum_{\ell=-J}^{-1} + \sum_{\ell=0}^0 + \sum_{\ell=1}^J \quad (\text{B.2})$$

Negative indices can be rewritten.

$$\begin{aligned} & \sum_{\ell=-J}^{-1} \sum_{n=|\ell|}^{|\ell|+J+1} (U_n^\ell, V_n^\ell) P_n^\ell(\sin \phi) \text{EXP}(i\ell\lambda) \\ &= \sum_{\ell=1}^J \sum_{n=\ell}^{\ell+J+1} (U_n^{-\ell}, V_n^{-\ell}) P_n^{-\ell}(\sin \phi) \text{EXP}(-i\ell\lambda) \\ &= \sum_{\ell=1}^J \sum_{n=\ell}^{\ell+J+1} (U_n^{-\ell}, V_n^{-\ell}) Y_n^{-\ell} \end{aligned} \quad (\text{B.3})$$

Wind components are real variables, so (95:25)(15:689):

$$(U_n^{-\ell}, V_n^{-\ell}) = (-1) (U_n^\ell, V_n^\ell)^* \quad (\text{B.4})$$

Complex conjugate is denoted by $*$. From (72:495):

$$Y_n^{-\ell} = (-1)^{-\ell} (Y_n^{\ell})^* \quad (\text{B.5})$$

Therefore, the negative ℓ -summation becomes:

$$\sum_{\ell=1}^J \sum_{n=\ell}^{\ell+J+1} (U_n^{\ell}, V_n^{\ell})^* (Y_n^{\ell})^* \quad (\text{B.6})$$

$$\begin{aligned} &= \sum_{\ell=1}^J \sum_{n=\ell}^{\ell+J+1} \{ [\operatorname{Re}(U_n^{\ell}, V_n^{\ell})] P_n^{\ell}(\sin\phi) (\cos\ell\lambda) \\ &\quad + [-i \operatorname{Im}(U_n^{\ell}, V_n^{\ell})] P_n^{\ell}(\sin\phi) (-i \sin\ell\lambda) \\ &\quad + [-i \operatorname{Im}(U_n^{\ell}, V_n^{\ell})] F_n^{\ell}(\sin\phi) (\cos\ell\lambda) \\ &\quad + [\operatorname{Re}(U_n^{\ell}, V_n^{\ell})] P_n^{\ell}(\sin\phi) (-i \sin\ell\lambda) \} \quad (\text{B.7}) \end{aligned}$$

U and V are real numbers; the real part of the summation with conjugates is the same without the conjugates. The real part of Eq (B.6) can be expressed as follows:

$$\operatorname{Re} \sum_{\ell=1}^J \sum_{n=\ell}^{\ell+J+1} (U_n^{\ell}, V_n^{\ell}) Y_n^{\ell} \quad (\text{B.8})$$

Therefore, the spectral wind equation becomes a summation over positive indicies. Spectral wind components are determined with the following expression:

$$(U,V) = (u,v)\cos\phi$$

$$= \sum_{n=0}^{J+1} (U_n^0, V_n^0) P_n^0(\sin\phi) + \operatorname{Re} \left[2 \sum_{\ell=1}^J \sum_{n=\ell}^{\ell+J+1} (U_n^\ell, V_n^\ell) P_n^\ell(\sin\phi) \operatorname{EXP}(i\ell\lambda) \right] \quad (\text{B.9})$$

Let $A = 1$ if $\ell = 0$; $A = 2$ otherwise.

$$(U,V) = (u,v)\cos\phi = \operatorname{Re} \sum_{\ell=0}^J A \sum_{n=\ell}^{\ell+J+1} (U_n^\ell, V_n^\ell) P_n^\ell(\sin\phi) \operatorname{EXP}(i\ell\lambda) \quad (\text{B.10})$$

Associated Legendre Polynomials

P_n^ℓ are associated Legendre polynomials, normalized as in (9).

$$P_n^\ell(x) = \frac{(-1)^{\ell+n}}{2^n n!} \left(\frac{(2n+1)(n-\ell)!}{2(n+\ell)!} \right)^{\frac{1}{2}} (1-x^2)^{\frac{\ell}{2}} \frac{d^{\ell+1}}{dx^{\ell+1}} (1-x^2)^n \quad (\text{B.11})$$

To generate numerical values, the model uses the recursion relation (95):

$$x P_n^\ell(x) = \epsilon_{n+1}^\ell P_{n+1}^\ell(x) + \epsilon_n^\ell P_{n-1}^\ell(x) \quad (\text{B.12})$$

where

$$\epsilon_n^\ell = \left(\frac{n^2 - \ell^2}{4n^2 - 1} \right)^{\frac{1}{2}} \quad (\text{B.13})$$

Belousov (9) shows the relation in the form:

$$P_n^m(x) = 2 a_n^m x P_{n-1}^m(x) - b_n^m P_{n-2}^m(x) \quad (B.14)$$

where

$$a_n^m = \frac{1}{2} \left(\frac{4n^2-1}{n^2-m^2} \right)^{\frac{1}{2}} \quad \text{and} \quad b_n^m = \left(\frac{(2n+1)(n-m-1)(n+m-1)}{(2n-3)(n-m)(n+m)} \right)^{\frac{1}{2}}$$

Factoring $2 a_n^m$ from both terms on the right side of Eq (B.14) gives the following:

$$P_n^m(x) = \frac{x P_{n-1}^m(x) - \left(\frac{(n-m-1)(n+m-1)}{(2n-3)(2n-1)} \right)^{\frac{1}{2}} P_{n-2}^m(x)}{\left(\frac{n^2-m^2}{4n^2-1} \right)^{\frac{1}{2}}} \quad (B.15)$$

Let $n \rightarrow n+1$ and $m \rightarrow \ell$.

$$P_{n+1}^\ell(x) = \frac{x P_n^\ell(x) - \left(\frac{(n-\ell)(n+\ell)}{(2n-1)(2n+1)} \right)^{\frac{1}{2}} P_{n-1}^\ell(x)}{\left(\frac{(n+1)^2 - \ell^2}{4(n+1)^2 - 1} \right)^{\frac{1}{2}}} \quad (B.16)$$

Substituting Eq (B.13) into Eq (B.16), gives the following form of Eq (B.12):

$$P_{n+1}^\ell(x) = \frac{x P_n^\ell(x) - \epsilon_n^\ell P_{n-1}^\ell(x)}{\epsilon_{n+1}^\ell} \quad (B.17)$$

Algorithm

The algorithm for computing wind vector components uses double precision calculations because the finite summation involves addition and subtraction of 992 terms per component.

1. Specify ϕ and λ .
2. Compute ϵ_n^λ .
3. Compute $P_{n+1}^\lambda(\sin\phi)$ from the recursion relation, Eq (B.17).
4. Compute $\text{EXP}(i\lambda) = \cos\lambda + i \sin\lambda$.
5. Compute (U,V) with Eq (B.10).
6. Compute $(u,v) = (U,V)/\cos\phi$.

Appendix C

Cloud Height Models

The height of a stabilized nuclear cloud in the atmosphere depends primarily on the weapon yield, atmospheric properties that affect cloud buoyancy and winds above the burst. Generally, cloud height increases with increasing weapon yield. Atmospheric nuclear weapons tests provided data for empirical fits to cloud height. The most recent and comprehensive correlations of visible cloud top and bottom height data are simple power laws (80).

$$H_{\text{top}} = c W^d \quad (\text{C.1})$$

$$H_{\text{bot}} = a W^b \quad (\text{C.2})$$

where

W is kilotons yield
H is meters above ground

$$a = 2228 \quad b = 0.3463 \quad W \leq 4.07$$

$$a = 2661 \quad b = 0.2198 \quad W > 4.07$$

$$c = 3597 \quad d = 0.2553 \quad W \leq 2.29$$

$$c = 3170 \quad d = 0.4077 \quad 2.29 < W \leq 19$$

$$c = 6474 \quad d = 0.1650 \quad W > 19$$

Yield-dependent heights are plotted in Figure C-1.

By comparison, the WSEG and AFIT codes use the following equation for height of the radioactive cloud center (19)(86).

$$HC = 44.0 + 6.1 \ln Y - 0.205 (\ln Y + 2.42) |\ln Y + 2.42| \quad (\text{C.3})$$

Figure C-1. Cloud Height vs Weapon Yield

where

Y is megatons yield
HC is kilofeet above ground

Figure C-1 shows that WSEG's equation puts the radioactive cloud near the bottom of the visible cloud. Early nuclear cloud data suggested that the fallout cloud was in the lower part of the visible cloud (92). For yields above 1 megaton, WSEG's predicted cloud height is notably lower than other models.

DELFIIC raises thousands of wafers filled with different sized particles to various heights by stabilization time. Particle sizes are generally gravity-sorted in the initial cloud. Figure C-1 shows the average height of wafers containing the DELFIIC default distribution's activity-median size (38 μm radius) in stabilized DELFIIC clouds. The following equations were derived from DELFIIC calculations of wafer heights in stabilized clouds (11)(53):

$$H_p = S D_p + B \quad (\text{C.4})$$

where

H_p is average height of DELFIIC wafer centers (meters)

D_p is particle diameter (μm)

$$S = \text{EXP} [1.574 - 0.01197 \ln W + 0.03636 (\ln W)^2 \\ - 0.0041 (\ln W)^3 + 1.965 \times 10^{-4} (\ln W)^4]$$

$$B = \text{EXP} [7.889 + 0.34 \ln W + 0.001226 (\ln W)^2 \\ - 0.005227 (\ln W)^3 + 4.17 \times 10^{-4} (\ln W)^4]$$

The dashed lines in Figure C-1 are the cloud top and bottom heights used by Turco and others to predict the "nuclear winter" (105):

$$Z_{\text{top}} = 21 Y^{0.2} \quad (\text{C.5})$$

$$Z_{\text{bot}} = 13 Y^{0.2} \quad (\text{C.6})$$

where

Z is kilometers above ground.

Appendix D

Polynomials for Laurent Series Constants

Laurent series constants are used to compute r and dr/dt in the dose rate equation.

$$r = \sum_{i=1}^6 C_i t^{i-6} + C_7 t^{-\frac{1}{2}} \quad (D.1)$$

The constants, C_i , were derived by Colarco to enable smearing codes to rapidly determine particle size arriving on the ground from a specified height at a specified time (24). There are 1750 constants, 7 per altitude, 250 altitudes.

Each of the seven constants, C_i , was correlated with height (H_k) in kilometers (3). Seven polynomial fits were developed: one for each constant. Each polynomial for a C_i is 6th degree in height, containing seven constants (D_{ij} , $j = 1, 7$).

$$C_i = D_{i1} + D_{i2} H_k + D_{i3} H_k^2 + D_{i4} H_k^3 + D_{i5} H_k^4 + D_{i6} H_k^5 + D_{i7} H_k^6 \quad (D.2)$$

Table D-1 shows the polynomial constants, D_{ij} . Figures D-1 and D-2 show r and dr/dt computed two ways: using tabular C_i and using Eq (D.2). The figures show a family of curves for the same initial cloud heights published by Bridgman (19). Small magnitude coefficients (C_1 - C_3) are not reproduced by Eq (D.2) as well as large magnitude coefficients (C_4 - C_7) at altitudes $\lesssim 4$ kilometers.

Appendix E

Crosswind Integration of Spatial Distribution

The two-directional spatial distribution function defines how activity is distributed in the cloud horizontally.

$$F_{xy} = \int_0^{\infty} f(x,y,t) dt \quad (E.1)$$

The integral was solved by Bridgman (19) using normal distributions in two directions and a constant unidirectional wind.

$$F_{xy} = \frac{1}{\sqrt{2\pi} \sigma_y V_x} \text{EXP} \left(-\frac{1}{2} \frac{y^2}{\sigma_y^2} \right) = \frac{F_y}{V_x} \quad (E.2)$$

The term $(1/V_x)$ comes from the transformation of the integration variable from t to x , and F_y is a normalized Gaussian distribution in the crosswind (y) direction.

$$\int_{-\infty}^{\infty} F_{xy} dy = \frac{1}{V_x} \quad (E.3)$$

If the wind is not constant and unidirectional, a more general result is derived. With variable winds, the spatial distribution function is expressed as follows:

$$F_{xy} = \frac{1}{\sqrt{2\pi} \sigma_v} \text{EXP} \left(-\frac{1}{2} \left(\frac{x V_y - y V_x}{\sigma_v} \right)^2 \right) \quad (E.4)$$

Figure E-1 illustrates the positions of wind vector components, the ground point (x,y) and the crosswind direction.

Integrating F_{xy} in the crosswind direction gives the following:

$$\int_{C'}^C F_{xy} ds = \int_{C'}^C F_{xy} \left(\frac{ds}{dx} \right) dx \quad (E.5)$$

If \vec{r} is a vector in the crosswind direction,

$$\vec{r} = x\hat{i} - \frac{V_x}{V_y} x\hat{j} \quad (E.6)$$

and ds/dx is defined by (58):

$$\frac{ds}{dx} = \left(\dot{\vec{r}} \cdot \dot{\vec{r}} \right)^{\frac{1}{2}} = \left[1 + \left(\frac{V_x}{V_y} \right)^2 \right]^{\frac{1}{2}} \quad (E.7)$$

The integral becomes:

$$\int_{-\infty}^{\infty} \frac{1}{\sqrt{2\pi} \sigma_V} \text{EXP} \left[-\frac{1}{2} \left(\frac{x V_y - y V_x}{\sigma_V} \right)^2 \right] \left[1 + \left(\frac{V_x}{V_y} \right)^2 \right]^{\frac{1}{2}} dx \quad (E.8)$$

$$= \frac{\left[1 + \left(\frac{V_x}{V_y} \right)^2 \right]^{\frac{1}{2}}}{\sqrt{2\pi} \sigma_V} \int_{-\infty}^{\infty} \text{EXP} \left[-\frac{1}{2} \left(\frac{x V_y - y V_x}{\sigma_V} \right)^2 \right] dx \quad (E.9)$$

On CC', $y = (-V_x/V_y) x$, so the integral in Eq (E.9) becomes:

$$\int_{-\infty}^{\infty} \text{EXP} \left[-\frac{1}{2} \frac{x^2 \left(V_y + \frac{V_x^2}{V_y} \right)^2}{\sigma_V^2} \right] dx \quad (E.10)$$

Figure E-1. Wind and Hotline Geometry

The above integral Eq (E.10) is solved analytically (88):

$$= \frac{\sqrt{2\pi} \sigma_v}{v_y + \frac{v_x^2}{v_y}} \quad (\text{E.11})$$

Therefore,

$$\int_{C'}^C F_{xy} ds = \frac{\left(1 + \left(\frac{v_x}{v_y} \right)^2 \right)^{\frac{1}{2}}}{v_y + \frac{v_x^2}{v_y}} = (v_x^2 + v_y^2)^{-\frac{1}{2}} \quad (\text{E.12})$$

This solution reduces to $(1/v_x)$ or $(1/v_y)$ when a constant wind is unidirectional along the x or y axis. The constant wind result was derived by Bridgman and Bigelow (19).

Appendix F

Method to Compute Dose Rate at Arbitrary Coordinates

To compute dose rate at any point (x,y) downwind of the burst, it is necessary to identify the hotline point (X,Y) at the intersection of the net wind and crosswind lines. The point (x,y) lies on the crosswind line. See Figure IV-5. This appendix describes a way to find the hotline point associated with any ground point by marching along the hotline, computing the angle between the net wind and crosswind directions, until a right angle is found. The hotline point (X,Y) is simply bracketed between two discrete hotline points, and then determined explicitly, without resorting to a numerical convergence scheme.

Figure F-1 shows a hypothetical hotline, with net wind and crosswind lines drawn for three different hotline points:

(X,Y) is the hotline point on a net crosswind line to (x,y) .

(X_i,Y_i) is the hotline point upwind of (X,Y) .

(X_{i+1},Y_{i+1}) is the hotline point downwind of (X,Y) .

The net wind vector from burst point $(0,0)$ to (X,Y) is OH : HF is the net crosswind line that is perpendicular to OH . The point (x,y) is on HF . The coordinates (X,Y) can be determined by finding the point (X,Y) that makes HF normal to OH . Following are line segments:

$$OA = (X_1^2 + Y_1^2)^{\frac{1}{2}} \quad (F.1)$$

$$AF = [(X_i - x)^2 + (Y_i - y)^2]^{\frac{1}{2}} \quad (F.2)$$

$$OF = (x^2 + y^2)^{\frac{1}{2}} \quad (F.3)$$

The line OF is fixed. The angle θ_i changes to θ_{i+1} when (X_i, Y_i) changes to (X_{i+1}, Y_{i+1}) . The angle θ_i is determined from the cosine law for triangles:

$$\cos \theta_i = \frac{OA^2 + AF^2 - OF^2}{2 \cdot OA \cdot AF} \quad (F.4)$$

To find (X, Y) , it is necessary to march along the hotline, computing $\cos \theta$ at each hotline point. When $\cos \theta > 0$, $\theta = \theta_{i+1}$ and $\theta_{i+1} < \pi/2$, so (X, Y) , the vertex of the right triangle OH-HF-OF, is between (X_i, Y_i) and (X_{i+1}, Y_{i+1}) . Assuming a piecewise linear hotline, (X, Y) can be determined by finding ΔX , the distance from X_i to X ; see Figure F-2.

$$X = X_i + \Delta X \quad \text{and} \quad Y = Y_i + \Delta Y \quad (F.5)$$

$$m = \frac{\Delta Y}{\Delta X} = \frac{(Y_{i+1} - Y_i)}{(X_{i+1} - X_i)} \quad (F.6)$$

$$\Delta Y = m \Delta X \quad (F.7)$$

Since OH is perpendicular to HF, the slopes of both lines are related.

$$\frac{y - Y}{x - X} = - \frac{X}{Y} \quad (F.8)$$

$$X^2 - Xx + Y^2 - Yy = 0 \quad (F.9)$$

Substituting Eq (F.5) for X and Y :

$$(X_i + \Delta X)^2 - (X_i + \Delta X) x + (Y_i + m \Delta X)^2 - (Y_i + m \Delta X) y = 0 \quad (F.10)$$

Figure F-2. Hotline Segment

$$A (\Delta X)^2 + B \Delta X + C = 0 \quad (F.11)$$

where

$$A = 1 + m^2 \quad (F.12)$$

$$B = 2 X_i + 2 m Y_i - x - m y \quad (F.13)$$

$$C = X_i^2 + Y_i^2 - x X_i - y Y_i \quad (F.14)$$

The quadratic Eq (F.11) can be solved explicitly for the two roots:

$$\Delta X_{\pm} = \frac{-B \pm (B^2 - 4AC)^{\frac{1}{2}}}{2A} \quad (F.15)$$

Since the hotline segment is represented with line AB, the correct root is the value of ΔX that places $(X_i + \Delta X, Y_i + \Delta Y)$ on AB. In Figure F-3, $X_i + \Delta X_+$ is in segment AB. The other root also produces a right angle at (X,Y) , but it does so by placing (X,Y) outside the AB segment.

The above method was verified by computing dose rates at arbitrary coordinates surrounding a curved hotline from a megaton cloud. Figure IV-9 is a three dimensional plot of downwind dose rates computed with this technique. Peak dose rates occur on the hotline and values decrease normally in crosswind directions.

Figure F-3. Hotline with Root Locations

Appendix G

Function Minimization Method to Fit Particle Size Distribution Data

This appendix describes a technique to fit particle size distribution data points with a trimodal log-normal function. The technique requires minimization of the sum of the squares of differences between data points and functional values. The technique was used twice in this study: (1) to fit points in the measured size spectrum published by Carey and Sigurdsson (21), and (2) to fit size distribution data points that were back-calculated with the ashfall equation and actual fallout data.

The measured size distribution was digitized from the histogram shown in (21), yielding twenty values of grain size and corresponding weight fraction. At the top of each histogram bar, the average radius was computed, and used with the frequency for that range of particle sizes. Twenty data points were obtained.

The data points were fitted by minimizing the sum of twenty residuals; squared differences between data points and values of a trimodal log-normal function. See Eq (5.1). The following function was minimized within a nine parameter hyperspace constrained by upper and lower bounds on the log-normal function parameters.

$$F = \sum_{j=1}^{20} [M(r_j) \cdot r_j - N(r_j) \cdot r_j]^2 \quad (G.1)$$

where

$N(r_j)$ = measured particle size distribution function for twenty
different particle radii
 $M(r_j)$ = trimodal log-normal function
 r_j = particle radius

The distribution functions $M(r_j)$ and $N(r_j)$, were weighted with r_j to facilitate selection of search limits on the hyperspace. This method produced an excellent fit to the measured data; the mean difference between $N(r_j) \cdot r_j$ and $M(r_j) \cdot r_j$ was 0.013 for the fit shown in Figure V-17. Log-normal function parameters are in Table V-3.

Isomass calculations with the ashfall equation and $M(r_j)$ generally agreed with ashfall data, but they did not replicate the Ritzville bulge. However, preliminary calculations, using the discontinuous histogram, showed that multiple modes in the mass size distribution produced multiple maxima in downwind ashfall. This observation suggested that a different particle size spectrum may have produced the bulge.

Using fallout data and the ashfall equation Eq (5.7), particle mass-size frequency was back-calculated at 13 points along the fallout centerline. The 13 points were then fitted with the trimodal log-normal function, Eq (5.1), using the same nine-parameter constrained minimization search technique used to fit the measured distribution data. The following function was minimized:

$$F = \sum_{j=1}^{13} [M'(r_j) \cdot r_j - N'(r_j) \cdot r_j]^2 \quad (G.2)$$

where

$N'(r_j)$ = back-calculated particle size frequency at discrete points
along the fallout centerline
 $M'(r_j)$ = trimodal log-normal function

This method produced an excellent fit to the back-calculated data; the mean difference between $N'(r_j) \cdot r_j$ and $M'(r_j) \cdot r_j$ was 0.021. The fit is shown in Figure V-22. Log-normal function parameters are in Table V-4.

Arthur Thomas Hopkins was born 8 January 1949 in Lewiston, Maine. He graduated from Lewiston High School and attended the Catholic University of America in Washington, D.C., where he earned Bachelor and Master of Science in Engineering degrees in Aerospace and Atmospheric Sciences. He entered the U.S. Air Force in July 1973 as a reentry physics project manager at the Space and Missile Systems Organization, Los Angeles, California. In 1977, he was assigned to the Defense Nuclear Agency, Washington, D.C., as a nuclear research officer. He entered the Air Force Institute of Technology Nuclear Engineering program in 1980, and earned the Master of Science in Nuclear Engineering degree in 1982. He is a member of Tau Beta Pi, the American Nuclear Society, the Health Physics Society, and the American Meteorological Society.

Permanent Address: 12 Whipple Street

Lewiston, Maine 04240

A new method has been developed to incorporate variable winds into fallout transport calculations. The method uses spectral coefficients derived by the National Meteorological Center. Wind vector components are computed with the coefficients along the trajectories of falling particles. Spectral winds are used in a two-step method to compute dose rate on the ground, downwind of a nuclear cloud. First, the hotline is located by computing trajectories of particles from an initial, stabilized cloud, through spectral winds, to the ground. The connection of particle landing points is the hotline. Second, dose rate on and around the hotline is computed by analytically smearing the falling cloud's activity along the ground. The feasibility of using spectral winds for fallout particle transport was validated by computing Mount St. Helens ashfall locations and comparing calculations to fallout data. In addition, an ashfall equation was derived for computing volcanic ash mass/area on the ground. Ashfall data and the ashfall equation were used to back-calculate an aggregated particle size distribution for the Mount St. Helens eruption cloud. Further validation was performed by comparing computed and actual trajectories of a high explosive dust cloud (DIRECT COURSE). Using an error propagation formula, it was determined that uncertainties in spectral wind components produce less than four percent of the total dose rate variance. In summary, this research demonstrated the feasibility of using spectral coefficients for fallout transport calculations, developed a two-step smearing model to treat variable winds, and showed that uncertainties in spectral winds do not contribute significantly to the error in computed dose rate.
